

EIO-Agents: The Missing Semantic Layer for AI Agent Evaluation

Fouad Bousetouane^{1,2}

Abstract

AI agents are entering production in increasingly consequential environments without a shared semantic standard for what their evaluations actually mean. Scores, traces, judge outputs, and multi-juror findings are increasingly used to justify readiness and release decisions, yet they often do not specify what evidence supports a claim, what that evidence can legitimately establish, or how the claim leads to a decision. This makes evaluation results difficult to compare across tools, challenge independently, or carry across organizational and regulatory boundaries.

We introduce **EIO-Agents**¹, an open specification for interoperable AI-agent evaluation built on two layers. The **Evaluation Intelligence Ontology (EIO)** provides the semantic layer: typed evidence, versioned behavioral predicates with evidence contracts, claims, witness rules, proof status, recurrence, and computable derivations for metrics, findings, controls, and PASS, REVIEW, or BLOCK decisions. The **Portable Evaluation Record (PER)** provides the system of record: a canonical, content-addressed representation of one evaluation that preserves the evidence-to-decision chain and can be re-derived, explained, and verified.

Scores summarize, juries interpret, and traces record, but none of them, by themselves, define what the evidence means or what it can prove. EIO provides that missing semantic contract, while PER preserves the resulting evaluation as a portable and verifiable system of record. The reference implementation makes these semantics executable through open-source projection, validation, verification, and explanation, enabling heterogeneous evaluation systems to produce results that remain meaningful beyond the tool that generated them.

As AI agents assume greater operational responsibility, evaluation must become more than a collection of scores and verdicts. It must become an accountable artifact whose meaning, evidence, limitations, and decisions can be consistently understood and independently checked.

¹<https://github.com/ProofAgent-ai/eio-agents>

1 Introduction

AI agents no longer only generate text. They call tools, retrieve external context, access enterprise resources, change the state of real systems, coordinate with other components, and make decisions inside regulated or consequential workflows. As their authority increases, the results of their evaluations become consequential artifacts in their own right. A dashboard that reads 92, or a jury that labels an agent “unsafe”, can decide whether that agent is deployed.

Evaluation practice has advanced quickly to meet this shift. Interactive benchmarks, adversarial harnesses, LLM judges, multi-juror panels, tracing systems, and human review now produce more evaluation output than ever before [16, 31, 12, 29, 17, 30, 28, 5, 3]. Each of these tools solves an important part of the problem. What they do not provide is a shared contract that connects evidence to claims and claims to decisions.

Most evaluation systems are designed to produce a verdict, not to state what that verdict rests on. A benchmark may report success, a harness a critical finding, a judge a hallucination score, and a tracing system the full trajectory. None of these artifacts by itself answers the question an engineer, auditor, regulator, or downstream system must eventually ask: *what exactly was observed, what does that observation establish, and why is the resulting decision justified?* Answering it requires following one chain:

$$\text{evidence} \rightarrow \text{meaning} \rightarrow \text{claim} \rightarrow \text{proof} \rightarrow \text{decision}.$$

Without a common model for that chain, two systems can report the same label while meaning different things, or different labels for the same behavior. A score is not evidence, and evaluation output should not be trusted simply because an evaluator produced it.

We call this the **semantic gap of agent evaluation**. Another benchmark, judge, or dashboard does not close it. Closing it requires a shared layer between raw evaluation output and the decisions built on it.

1.1 EIO and PER: semantics and record

This paper introduces **EIO-Agents**, an open specification for that layer. It has two tightly coupled parts:

EIO: the semantic layer. The Evaluation Intelligence Ontology defines the meaning of evaluation objects and the contracts between them. Its core chain is *Evidence* $\rightarrow$ *Predicate* $\rightarrow$ *Claim* $\rightarrow$ *Proof* $\rightarrow$ *Decision*. EIO specifies what counts as evidence, what behavior a predicate means, what evidence a claim must cite, whether that evidence can witness agent behavior, how proof status is computed, and how downstream metrics, findings, controls, and release decisions derive from claims.

PER: the system of record. The Portable Evaluation Record is the canonical representation of one evaluation under a particular EIO release. It carries the evidence references, claims, proof status, findings, metrics, provenance, limitations, controls, explanations, release recommendation, and a content digest. PER is not a presentation format for a dashboard; it is the durable record from which a presentation or decision can be re-derived.

The relationship is simple: **EIO defines meaning; PER preserves meaning**. Figure 1 shows the architecture. Existing evaluators are not replaced. They become producers of evidence and claims under a shared semantic contract. Their outputs can then be compared, exchanged, audited, and independently checked without forcing every evaluator to use the same implementation.

The design is organized around four separations that current evaluation output often collapses:

**Observation $\neq$ Evidence. Evidence $\neq$ Proof. Judgment $\neq$ Proof.
Score $\neq$ Decision.**

A malicious user message shows that an attack was attempted, not that the agent followed it. A judge can identify a likely policy violation, but its opinion cannot make a missing tool call appear in the trace. A metric summarizes many claims, but it cannot replace the evidentiary status of the claim that should drive a release. EIO encodes each of these distinctions as a machine-checkable rule (Section 3).

1.2 Contribution and scope

The contribution is not a new evaluator. It is a common semantic substrate for evaluation systems. Specifically, this paper contributes: (1) an evidence-to- decision ontology for AI-agent evaluation; (2) computable witness, proof, reliability, and release semantics; (3) PER, a portable and re-derivable evaluation system of record; and (4) an open-source reference implementation showing how heterogeneous evaluation output can be projected, validated, explained, and verified.

We use “standard” to mean an open specification designed for common adoption, not an already recognized standards-body standard. EIO-Agents is the first step toward that goal; Section 7 lays out the path from open specification to common standard.

Figure 1: **The EIO-Agents architecture.** Evaluation systems produce evidence; EIO supplies the semantic contract that turns evidence into claims, proof status, and decisions; PER preserves the resulting evaluation as one content-addressed system of record. Metrics, findings, controls, and release recommendations are views over claims rather than independent facts.

2 Why Existing Evaluation Output Is Not a System of Record

The current agent-evaluation stack is strong at execution and weak at semantic portability: its components are complementary, but each terminates in evaluator-specific scores or labels.

2.1 Verdicts without a common evidence contract

Interactive benchmarks such as AgentBench, WebArena, SWE-bench, and τ -bench moved evaluation to trajectories, tools, and repeated trials [16, 31, 12, 29], frameworks such as HELM, the LM Evaluation Harness, and Inspect standardize execution and logging [15, 10, 27], and adversarial harnesses add multi-turn traps and audit rules [5, 3, 6]. LLM judges scale semantic evaluation [17, 30], and juries reduce some single-judge effects [28]. These systems produce valuable evidence and solve real parts of the evaluation problem. What they do not share is a rule for what a given piece of evidence may establish. A unanimous jury cannot turn a user prompt into proof of an agent action, or a fabricated quotation into a transcript fact.

2.2 Traces and provenance are necessary, not sufficient

EARL [1], PROV-O [14], in-toto [25], OpenTelemetry [19], model cards [18], and assurance cases [26, 13, 2] represent outcomes, provenance, traces, reports, and arguments.

EIO builds on these ideas and targets a narrower missing contract: the semantics of AI-agent evaluation itself. A trace records what happened; it does not define what the observation means. Provenance answers *where an artifact came from*. EIO asks *what does this evidence mean for this behavioral claim, and what decision is allowed to follow?*

2.3 From proprietary reports to portable evaluation intelligence

Figure 2 captures the intended shift. EIO does not require evaluators to adopt one benchmark or scoring model; it requires them to make explicit which predicate is asserted, what evidence supports it, who decided it, and with what proof status. PER preserves that meaning in a portable record.

Figure 2: **From evaluator-specific output to portable evaluation intelligence.** Evaluators may keep their own methods, prompts, judges, and scoring logic. EIO standardizes the semantic contract between evidence, claims, proof, and decisions; PER preserves one canonical record per evaluation.

3 The Semantic Chain

EIO organizes evaluation meaning as a five-step chain (Figure 3). In plain terms:

Evidence is what was actually observed: a span of the agent’s answer, a tool-call receipt, a change of system state, a human sign-off.

A predicate is the standardized behavior being tested, for example `untrusted-instruction-execution`: did the agent act on an instruction it should not have trusted?

A claim states that a particular predicate passed or failed in a particular evaluation, at particular turns, citing particular evidence.

Proof says whether that evidence satisfies EIO’s rules strongly enough to establish the claim.

A decision is what follows from the claims: PASS, REVIEW, or BLOCK.

Formally, each step is a typed object and each transition is governed by a rule. Evidence is a typed, content-addressed reference into the evaluation archive. A predicate is versioned and carries an *evidence contract* that states what a decision must cite. A claim records its state, its evidence, its decider, and its provenance. Proof is computed from the decider, the evidence, and the reliability record, and is either PROVEN or UNPROVEN. A decision is a

view over claims that names its decisive conditions. Sections 4 and 5 make each of these precise.

Figure 3: **The EIO semantic chain.** Evidence, predicates, claims, proof, and decisions are distinct, typed objects related by explicit rules. The four boxes below the chain name the distinctions that evaluation output usually collapses and that EIO keeps apart.

The chain makes the four distinctions of Section 1 operational.

Observation $\neq$ Evidence. The archive contains everything the agent saw and did. Only part of it is evidence about the agent. A user turn, including text planted by an adversarial scenario, is typed `USER_INPUT`; a retrieved document is `RETRIEVAL`; a policy text is `POLICY_SPAN`. All three may be cited as context, for example to show that an injected instruction existed, but none of them can witness what the agent did.

Evidence $\neq$ Proof. A ref may be valid evidence and still fail to prove a claim. A turn-level reference to the agent’s answer locates the answer but does not anchor the behavior to an exact span; a tool result proves the effect of a call only when the call itself is cited. Proof requires a decider whose decision can be proven and at least one *witnessing, anchored* reference.

Judgment $\neq$ Proof. A semantic resolver, such as an LLM jury, is valuable precisely because it can decide claims that code cannot. Its decisions are recorded, cited, and shown to reviewers. Jury consensus, however, is not proof: consensus changes confidence in an interpretation; it does not change the nature of the evidence. Under the current specification, semantic decisions are therefore never `PROVEN`, and on their own they can raise a release recommendation to `REVIEW` but never to `BLOCK`. This is a deliberate trade-off, not a claim that semantic failures are harmless. Some harms, such as a fabricated clinical fact,

can only be detected semantically. EIO does not suppress them: they remain findings with their severity and evidence, and REVIEW means the agent is *not* released without a human decision. What EIO refuses is an automatic BLOCK resting only on model judgment that no witnessing evidence supports. A deployer that wants such failures to stop a release may declare a prohibited use case or require human adjudication, whose decisions can be PROVEN.

Score $\neq$ Decision. Scores, axes, and readiness are computed from claims, and caps link scores back to the claims that caused them. The release recommendation, however, is not a threshold on a score. A readiness below its floor without a proven failure gives REVIEW; BLOCK requires a PROVEN failure or a declared prohibited use case.

4 EIO: The Semantic Layer

EIO is not a scoring model and not a replacement for an evaluation harness. It has three parts. A *vocabulary* names standard concepts and behavioral predicates. *Contracts* state what evidence each predicate requires and which kinds of evidence may witness agent behavior. *Executable validation* recomputes witness status, evidence contracts, claim validity, proof status, derived views, and release decisions in software. EIO does not merely name behaviors. It defines the rules under which evidence is allowed to establish those behaviors.

The ontology is published as versioned YAML modules with JSON Schemas and a JSON-LD context [23]; the full schema is browsable online [21]. Each of its 41 modules is pinned by exact version and SHA-256 digest, so changing the meaning of a predicate or an evidence contract changes the semantic release, not just the prose around it.

4.1 Design commitments

Five commitments shape the specification. *Claims are the only facts*: metrics, findings, controls, and the release recommendation cite claims and add none. *Computed, not declared*: witness flags, identifiers, proof status, and release states are recomputed, and a producer’s flag is never trusted. *Unknown is not pass*: undecided predicates never count as passes, and evaluator failures are not charged to the agent. *Meaning is versioned*: changing a predicate or its contract is a new version. *Evaluator neutrality*: any evaluator that emits a conforming bundle can produce a record.

4.2 Evidence, sources, and anchors

The central question for any piece of evidence is whether it can show what the *agent* did, as opposed to what the agent was told or what a judge believes. EIO answers it with three typed attributes. An evidence ref r points into the evaluation archive and has an evidence type $\kappa(r)$, a source type $\sigma(r)$, and an anchor $\alpha(r)$; its identifier is a digest of its content.

Evidence types separate what can prove agent behavior (agent spans, tool receipts, state facts and transitions, typed absences, calculations, human sign-offs) from what cannot (user input, retrievals, policy spans, provenance entries). Source types separate the agent’s own answers and tool calls, paired tool results, the state ledger, and human review, which may witness, from user input, retrievals, policy sources, harness signals, and JUROR_INFERENCE,

a juror’s proposed citation found in no source, which never witness. Anchors state how precisely a ref is located: **exact**, **casefold**, **receipt**, and **computed** anchors can witness, while **line**, **turn**, **document**, and **none** only locate. Tool arguments are stored as a digest and a JSON pointer, and excerpts are capped and pattern-redacted. Table 1 gives the counts.

4.3 The witness rule

The witness rule decides whether a ref can witness agent behavior. Let $\mathcal{K}^+$ be the evidence types that can prove behavior, $\mathcal{S}^+$ the source types that may witness, and $\Gamma(\kappa)$ the source types compatible with evidence type κ . Then

$$\text{witness}(r) = [\kappa(r) \in \mathcal{K}^+] \wedge [\sigma(r) \in \mathcal{S}^+] \wedge [\sigma(r) \in \Gamma(\kappa(r))] \wedge \text{paired}(r), \quad (1)$$

where $\text{paired}(r)$ is true unless $\sigma(r)$ is **TOOL_RESULT**, in which case every claim that cites r must also cite the agent’s tool call with the same turn and call index. A ref is *witnessing and anchored* when

$$\text{wa}(r) = \text{witness}(r) \wedge \alpha(r) \in \{\text{exact}, \text{casefold}, \text{receipt}, \text{computed}\}. \quad (2)$$

Figure 4 shows the rule as a matrix computed from the EIO release data. Of the 110 pairs of evidence type and source type, 11 witness, 3 witness only with a paired tool call, 13 are compatible but never witness, and 83 are incompatible. The rule is part of the release, and the library computes it for every ref; the verifier recomputes it and rejects any record whose flags disagree.

4.4 Predicates and evidence contracts

A predicate is a versioned proposition with a polarity. EIO currently has 58 predicates: 49 risk predicates, whose failure is a violation; 7 safeguard predicates, whose failure is a missing safeguard; and 2 observation predicates, whose failure is an observation and never a violation. Each predicate declares when it applies and when it is violated, an unknown policy, its resolvers, and an *evidence contract*: the evidence groups a decision must cite, the types forbidden as proof of agent behavior, a minimum number of references, and a scope. For **untrusted-instruction-execution**, the contract requires something the agent did (a tool receipt, an agent span, or a state transition) and the untrusted content itself (a user input or a retrieval), which is required as context and forbidden as proof. Predicates are grouped into eight risk modules, one of which concerns the reliability of the evaluator itself (Figure 6a).

4.5 Claims and claim states

A claim c is the tuple

$$c = (p, v, T, s, E, d, \pi), \quad (3)$$

where p is a predicate, v its version, T the turns of the run it applies to, s its state, E the evidence refs it cites, $d \in \{\text{deterministic}, \text{semantic}, \text{human}\}$ its decider, and π its provenance: the EIO module and module digest, the evaluation plan digest, and, for semantic claims,

		<i>may witness (5)</i>					<i>never witness (5)</i>				
		AGENT_ANSWER	AGENT_TOOL_CALL	TOOL_RESULT	STATE_LEDGER	HUMAN_REVIEW	USER_INPUT	RETRIEVAL	POLICY_SOURCE	HARNESS_SIGNAL	JUROR_INFERENCE
<i>can prove (7)</i>	AGENT_SPAN	✓									✗
	TOOL_RECEIPT		✓	▨							
	STATE_FACT				✓						
	STATE_TRANSITION				✓						
	TYPED_ABSENCE	✓	✓	▨	✓		✗	✗	✗	✗	
	CALCULATION	✓	✓	▨	✓		✗	✗	✗	✗	
	HUMAN_SIGNOFF				✓						
<i>cannot (4)</i>	POLICY_SPAN								✗		
	PROVENANCE									✗	
	USER_INPUT					✗					
	RETRIEVAL						✗				

✓	witnesses agent behavior	▨	only with its paired tool call
✗	compatible, never witnesses	□	incompatible pair

Figure 4: **The witness rule of EIO**, computed from the release data by the reference library. Rows are evidence types and columns are source types. Only 11 of 110 pairs witness agent behavior outright, and 3 more witness only when the tool result is cited together with its agent tool call. A span whose source is `JUROR_INFERENCE`, a juror’s citation found in no source, is compatible with the span type and still never witnesses.

the model and seed. A claim’s identifier is a digest of the run, the predicate, its version, the turns, and the producer’s source key (null for a native claim), so re-deriving a record reproduces every identifier.

EIO defines seven claim states: `APPLICABLE_PASS` and `APPLICABLE_FAIL`, which are scored; `NOT_APPLICABLE` and `UNRESOLVED`, which are not; and `EVIDENCE_INVALID`, `EVIDENCE_INCOMPLETE`, and `EVALUATOR_ERROR`, which record that the evaluation failed, not the agent. An unknown outcome is never counted as a pass.

4.6 Resolvers

A resolver decides a claim. Deterministic resolvers check spans, receipts, state transitions, absences, policies, and arithmetic in code; semantic resolvers answer one bounded relation or one closed classification with a model; and a human resolver records an adjudication. Semantic resolvers are bounded by design: each answers one relation or one closed class, with evidence and counter-evidence, and abstains when the evidence does not distinguish the alternatives. A semantic resolver may decide only what deterministic resolvers left open, and a fact established by code is never re-decided by a model.

4.7 Proof status

Proof is a property of a claim. Let $\phi(c)$ be the claim’s declared fidelity to its predicate (`exact`, or a narrower proxy observation) and $\beta(c)$ its recurrence band (Section 4.8). The proof rule of EIO is

$$\begin{aligned} \text{proven}(c) \iff & d(c) \in \{\text{deterministic}, \text{human}\} \wedge \exists r \in E(c) : \text{wa}(r) \\ & \wedge (\phi(c) = \text{exact} \vee \beta(c) = \text{CONFIRMED}). \end{aligned} \quad (4)$$

Every other claim is `UNPROVEN`. A finding is `PROVEN` when at least one of its claims is. Figure 5a shows the rule as a decision path. The three conditions correspond to three different reasons a claim may fail to be proof: it was decided by a model, it cites nothing that can witness the behavior, or it is a proxy observation that did not reproduce. `PROVEN` means proven under the EIO evidence rules, not ground truth: a deterministic check can be wrong, and an archive can be wrong. What the rule guarantees is that a `PROVEN` claim rests on a code or human decision and on evidence that can witness agent behavior.

4.8 Reliability: occurrence and recurrence

Flagged scenarios can be re-run. EIO keeps two ledgers apart. The *occurrence* ledger records whether a behavior happened at least once with valid evidence; a later non-recurrence never withdraws it, because a breach that happened, happened. The *recurrence* ledger records whether the behavior reproduced across re-test passes. With r the number of passes in which a claim reproduced and n the number of passes run, the recurrence band is

Figure 5: **Proof and release in EIO.** (a) A claim is PROVEN only if it was decided by code or an identified human, cites a witnessing, anchored ref, and is either an exact observation of its predicate or a proxy observation that reproduced in every re-test. (b) Only a PROVEN failure or a declared prohibited use case can make the recommendation BLOCK. The same predicate leads to BLOCK in one reference run and REVIEW in another because the recurrence of the proxy observation differs.

$$\beta = \begin{cases} \text{CONFIRMED}, & n > 0 \text{ and } r = n, \\ \text{INTERMITTENT}, & 0 < r < n, \\ \text{UNCONFIRMED}, & n > 0 \text{ and } r = 0, \\ \text{NOT_RETESTED}, & n = 0. \end{cases} \quad (5)$$

The band matters for proof only for proxy observations: a narrower observation of a predicate becomes PROVEN only when it is CONFIRMED. The two ledgers answer different questions and do not conflict. The occurrence ledger answers *did the observed event happen?*, and a witnessed occurrence stays in the record, in its finding, and in any cap it triggers, whatever the re-runs show. The proof rule answers *does this observation establish the predicate?* A proxy observation is, by declaration, narrower than its predicate: a single witnessed occurrence establishes the proxy event but not the broader behavior the predicate names, and reproduction is the evidence EIO requires to bridge that gap. An exact observation needs no reproduction and is PROVEN from a single witnessed occurrence. A decision that changes under a metamorphic variant indicts the evaluator, not the agent. Reliability rates use the unbiased pass^k estimator $\binom{c}{k}/\binom{n}{k}$ [8, 29], and no rate is published below five tasks.

4.9 Views: metrics, findings, controls, and the release recommendation

Everything above the claims is a view. Each view is computed deterministically from claims and cites them.

Metrics and scores. Let C^{sc} be the claims in a scored state. A metric is a function of C^{sc} only, so not-applicable, unresolved, and evaluator-fault claims are excluded from every denominator. Axes and a readiness index are aggregated with limited compensation, and caps tie a score to the claim that caused it. Each cap names its claim, turn, and evidence ref.

Findings. Failed claims on one risk or safeguard predicate are promoted to a finding. A finding carries its claims, decider, proof status, recurrence band, and severity.

Controls. EIO maps predicates to controls in framework views. A control’s status is derived from the claims on its target predicates, and a violation resting only on proxy claims is never decisive. Every mapping is provisional and flagged for legal review: a control status expresses evidence relevance from one run, not legal conformity, certification, or attestation, and the verifier rejects a control summary that says “compliant”.

Release recommendation. Let $\mathcal{D}$ be the decisive conditions of an evaluation: caps, failed floors, triggered policy rules, and declared facts. Each condition k has an effect

$$\text{eff}(k) = \begin{cases} \text{BLOCK}, & k \text{ rests on a PROVEN failure, or } k \text{ is a declared prohibited use case,} \\ \text{REVIEW}, & \text{otherwise,} \end{cases} \quad (6)$$

and the recommendation is

$$\text{state} = \max_{k \in \mathcal{D}} \text{eff}(k), \quad \text{PASS} < \text{REVIEW} < \text{BLOCK}, \quad (7)$$

with state = PASS when $\mathcal{D}$ is empty. A claim whose decisive fact came only from a semantic resolver therefore has a maximum effect of REVIEW, whatever the size or agreement of the jury.

4.10 What the EIO release contains

Table 1 summarizes the release bundled with the reference library. Figure 6 shows how predicates are distributed across risk modules and how controls are distributed across the 30 framework views of the compliance crosswalk, which includes the EU AI Act [9], the NIST AI RMF [24], ISO/IEC 42001 [11], and the OWASP lists for LLM and agentic applications [20]. Thirty-six of the 58 predicates map to at least one control.

Item	Count	Item	Count
Modules, pinned by digest	41	Claim states	7
Predicates (risk, safeguard, obs.)	58 (49, 7, 2)	Recurrence bands	4
Evidence types (can prove)	11 (7)	Explanation templates	36
Source types (may witness)	10 (5)		
Resolvers (det., sem., human)	11 (8, 2, 1)	Domain modules	11
Framework views	30	Coverage obligations	126
Controls, all provisional	165	Reference cases (seeds)	45

Table 1: EIO at a glance. The release has `production_status:` `candidate`, and its ontology digest is `ed5389af5235e4b8`.

Figure 6: **Content of the EIO release.** (a) The 58 predicates by risk module and polarity. (b) The 165 controls of the compliance crosswalk by framework view. Every control is `mapping_status: provisional` with `legal_review_required: true`; a view expresses evidence relevance, not coverage of the full framework.

5 PER: The Portable Evaluation Record

If EIO is the semantic contract, PER is the system of record. A PER is the canonical record of what an evaluation established, under which semantics, from which evidence, and why. It preserves the evaluation’s identity, subject, and provenance; its evidence and claims with their proof status; its coverage and limitations; and the findings, metrics, controls, reliability, explanations, and release recommendation derived from those claims, all sealed by a content digest. A report summarizes an evaluation. PER preserves the state from which that report can be regenerated.

5.1 Record structure

A PER record has exactly 14 required top-level blocks and no others (Figure 7). Six blocks state identity and context: **header**, **provenance**, **subject**, **scope**, **limitations**, and **telemetry**. Three hold the facts: **evidence**, **claims**, and **coverage**. Five are views over claims: **findings**, **controls**, **scores**, **reliability**, and **release_recommendation**.

Figure 7: **Anatomy of a PER record.** Claims are the facts. Evidence refs are cited by claims, coverage counts them, and every view (findings, controls, scores, reliability, release recommendation) cites claim identifiers and adds no facts. The record digest is the SHA-256 of its canonical JSON bytes.

The header names the PER version and schema, the EIO release with its ontology digest and the digest of every module, and the converter that produced the record. A consumer

can therefore tell exactly which semantics a record was produced under. The `coverage` block states which coverage obligations of the evaluated domain were met and, for every obligation that was not, the cause of the silence, chosen in a fixed order from `UNREACHABLE`, `NOT_IMPLEMENTED`, `NEVER_SELECTED`, `PRECONDITION_ABSENT`, and `INCOMPLETE_COVERAGE`. A predicate that produced no claim can never render as a clean result.

5.2 Content addressing

A record’s digest is

$$\text{per_sha256} = \text{"sha256:"} \parallel \text{SHA256}(\text{JCS}(R)), \quad (8)$$

where JCS is the RFC 8785 canonical form [22] and bundle text is read as I-JSON [7]. Evidence refs, claims, and findings carry their own content-derived identifiers. The digest of a record changes when the archive changes, when any byte of the EIO release changes, when the PER schema version changes, or when the conversion code changes its output. Re-deriving a record therefore requires the same library version, which the header records.

5.3 Explanations and limitations

Every “why” in a PER record is rendered from one of 36 registered templates, never from model-written prose. An explanation object carries its template identifier, its parameters, a rendered summary, a basis (how many claims were applicable, passed, failed, not applicable, unresolved, or evaluator faults), ranked driver claims, and the cited evidence refs. Because explanations are rendered from parameters, the verifier can re-render each one and check it. The `limitations` block states what the evaluation could not capture, using a closed catalogue of 48 limitation identifiers; an identifier outside the catalogue fails the conversion. What the run did not establish is stated, not left as an absence.

5.4 Verification

PER records are meant to be checked, not trusted. The reference library provides three operations. `validate(record)` checks a record on its own against the PER JSON Schema and every EIO rule that can be recomputed from the record and the release. `verify(record, bundle)` adds source verification (check VER-5 of the specification), which recomputes from the bundle’s sources every ref and digest those sources determine, and then re-projects the bundle and compares digests. `explain(record, target)` prints the registered rendering for any score, finding, control, or the release recommendation. Table 2 groups the checks.

Group	Checks	What is recomputed
Schema and release	S1–S5, A1–A3	JSON Schema; claim schema; PER and EIO versions; module digests; every EIO identifier; domain and coverage
Evidence	E1–E4	Cited refs resolve; the witness rule for every ref; cited-refs hash; array orders
Claims	C1–C3	Claim identifiers; conditional parameters and votes; evidence contracts
Views	F1, K1, M1, L1	Findings and the precondition of PROVEN; control statuses; caps and drivers; reliability ledgers
Explanations	X1, X2	Re-rendering from registered templates; forbidden wording such as “compliant”
Decision	R1, R2	Gates; the release recommendation and its invariants
Record hygiene	T1, P1, N1, W1	Limitations catalogue; pointers; number forms; every string of the record fits its declared class
Derivation	D1–D3	Record digest; VER-5 over the bundle’s sources; byte-identical re-projection

Table 2: Verification checks of the reference library, grouped. The derivation checks D2 and D3 require the evaluation bundle.

Figure 8 shows verification as a loop. A producer projects a bundle into a record and publishes the record with its digest. A consumer, auditor, or registry re-derives the record from the same bundle and compares. Any change to the record that is not a change to the bundle is detected, and any change to a derived block that does not follow from the claims fails the semantic checks even before the digest is compared.

5.5 What verification establishes

A valid result with matching digests establishes two things. *Integrity*: the record is well formed, every derived block agrees with its claims and evidence under the bundled EIO release, and the digest is the digest of its canonical bytes. *Derivation*: projecting the given bundle with the same library version produces exactly this record, and the record’s refs agree with the bundle’s sources. Verification does not establish that the bundle came from a real run, that an agent or a jury would decide the same way again, that a PROVEN claim is true, or any certification or legal conformity. These limits are part of the specification, and the record itself says so.

Figure 8: **Verification by re-derivation.** The FIN_3 bundle projects to a record with digest sha256:7e944e75... and state BLOCK. Verifying the record against its bundle succeeds. A copy whose recommendation was edited from BLOCK to PASS fails the schema check (S1), the release invariant (R2: state PASS differs from the maximum effect BLOCK), and the re-projection check (D3), and verify exits with code 2.

6 Open-Source Reference Implementation: Making Semantics Executable

A standard that lives only on paper is easy to ignore. EIO-Agents is therefore also code: an open-source library that anyone can install and run. It does four things. It turns the output of any evaluator into a PER record, checks that the record follows the EIO rules, rebuilds the record from the original evidence to confirm nothing was changed, and answers “why?” for any score, finding, control, or release decision. The same four operations are available from the command line and from Python.

Command	What it does
<code>eio-agents project</code>	Turns an evaluation bundle into a canonical PER record.
<code>eio-agents validate</code>	Checks that the record obeys the EIO and PER rules.
<code>eio-agents verify</code>	Goes back to the source evidence, rebuilds what can be rebuilt, re-projects the record, and compares digests.
<code>eio-agents explain</code>	Traces a metric, finding, control, readiness score, or release decision back to its claims and evidence.

Table 3: The interface of the reference library. The same four operations are available from Python. The goal is not to hide evaluation complexity but to make its semantics inspectable.

Familiar evaluation words show why a semantic layer matters. Two tools may both report “hallucination” while testing different things: one checks that every cited figure appears in the retrieved documents, another asks a judge whether the answer “sounds made up”. In EIO the word is not enough; the producer must say which behavioral predicate it is asserting. The same holds for prompt injection, policy adherence, manipulation resistance, and, conceptually, for producer-defined notions such as drift or consistency, which are not EIO predicates today and would have to be mapped to one before they could enter a record.

Interoperability works through a declared mapping. Consider an external evaluator that emits `hallucination_rule = FAIL` on a transcript in which the agent cites a regulatory deadline that does not exist:

```
External evaluator: hallucination_rule = FAIL
                    | vendor adapter / reviewed crosswalk
                    v
eio.predicate.authority-or-deadline-invented
                    | exact evidence anchored to the transcript
                    v
EIO validates the evidence contract
                    v
Claim -> proof status -> PER
```

The trust boundary is explicit. The producer or adapter author declares what its evaluator output means, together with the fidelity of that mapping. EIO does not use fuzzy matching and does not guess the mapping. Once the mapping is declared, EIO validates whether the evidence, claims, proof status, derived metrics, and decisions obey the specification. Inside a record, a *metric* is a view over claims, a *finding* is a surfaced failed claim with its proof status, and a *release decision* is a deterministic view over decisive conditions. `explain` makes each of these visible:

```
eio-agents explain fin3.per.json eio.metric.hallucination-resistance
Hallucination Resistance 96.1: 2 of 16 applicable claims failed;
0 not applicable and 8 evaluator-fault claims are excluded.
```

The important object is not the number 96.1. It is the explanation: which claims were applicable, which failed, and which evaluator faults were excluded. Two evaluators do not need the same prompt, jury, or score. They need to make the same semantic commitments when they claim to have observed the same behavior.

A typical workflow is therefore:

```
Evaluator / Harness → Evaluation Bundle → EIO → PER
PER → validate / verify / explain → downstream consumers
```

The reference implementation is intentionally open because conformance cannot be a proprietary assertion. Producers should be able to test their own adapters; consumers should be able to verify the semantics they receive; and competing tools should be able to exchange evaluation records without trusting the original evaluator’s dashboard.

Appendix A walks through this workflow end to end on three reference evaluations: how 243 claims become a BLOCK decision, how a tampered record is caught, why the same score can lead to different decisions, and why a unanimous jury is still not proof.

7 From Open Specification to Common Standard

The ambition of EIO-Agents is deliberately larger than one evaluator or one platform: the semantic layer is useful only if records can cross those boundaries. That does not make EIO a de jure standard today. It makes standardization the design target. This section separates what is already technically enforceable from what still requires independent implementations, neutral governance, and broader adoption.

7.1 Interoperability by construction

The input to EIO-Agents is an *evaluation bundle*: sources (turns, answers, tool calls, retrievals, state), typed evidence, claims, ballots, and trials, in a schema any evaluator can emit. A harness, a benchmark runner, an LLM-judge pipeline, or a human review tool can produce a bundle directly or through an adapter that maps its own outcome vocabulary onto EIO predicates and declares the fidelity of each mapping. The adapter for the first producer lives in that producer’s code base, not in the library. EIO is meant to map to existing formats rather than replace them: EARL outcomes [1], PROV derivations [14], supply-chain attestations [25], and OpenTelemetry traces [19] each correspond to parts of a PER record.

Table 3 summarizes the interface a producer or consumer needs.

7.2 Versioning and governance

The specification has three version lines: the library, the EIO release it bundles, and the PER version it produces. Each library release bundles exactly one EIO release and one PER version. A change of meaning in EIO or PER, such as a new or changed predicate, evidence type, claim state, witness rule, release rule, scoring rule, or record field, is a normative change. It follows a public process: a proposal naming the affected identifiers and the effect on records and digests, at least 14 days of public comment, an implementation with regenerated digests and golden records, the approval of the specification maintainers, and a new EIO release. Framework mappings follow the same process and stay provisional until a legal review process exists.

The conformance machinery is part of the release. The golden records reproduce byte for byte across Python versions and hash seeds. A verifier self-test injects 31 defects into a valid record, among them a witness flag turned on for a user input, an unpaired tool result claimed as a witness, a release state lowered from BLOCK to REVIEW, and a control summary that says “compliant”, and requires that each is caught. Thirty-seven build gates check the EIO release itself, with 40 negative vectors that each gate must reject.

7.3 A first step toward standardization

EIO-Agents is the first step of a standardization effort, not its end point. The semantic core (the chain, the witness rule, the proof rule, and the release semantics) is fixed and executable today. The next steps turn an open specification into a common standard, and each one already has a concrete place in the roadmap:

- **Independent implementations.** The conformance suite, golden records, and verifier self-tests are published so that a second, independent implementation can be built and checked against the same digests.
- **Neutral governance.** The specification is designed to move to multi-party governance, for example a community group or a foundation, with the public change process described above.
- **Neutral vocabulary.** Identifiers move to a neutral namespace in one reviewed batch, so that every producer obtains fully schema-valid records.
- **Reference scoring.** A claims-derived reference scoring will sit beside producer scoring profiles; the proof and release rules already stand on their own.
- **Signed attestation.** Content addressing makes records tamper-evident; signatures will add who produced them.
- **Adjudicated cases and reviewed mappings.** The reference cases and framework mappings will grow into adjudicated test sets and legally reviewed crosswalks.

Throughout, the meaning of the core objects stays bounded by design: PROVEN is the outcome of the EIO evidence rule, and a control status expresses evidence relevance, not certification. Records may contain personal data and should be handled accordingly.

8 Conclusion

AI-agent evaluation has advanced rapidly in execution, judging, tracing, and benchmarking, but it still lacks a common semantic layer connecting evidence to claims and claims to consequential decisions. Without it, a number can travel farther than the evidence that justified it, and an evaluation can look rigorous while remaining difficult to reproduce or challenge.

EIO-Agents addresses this gap at the semantic boundary. EIO defines the vocabulary, contracts, and executable rules that connect evidence to predicates, claims, proof status, metrics, findings, controls, and decisions. PER makes one evaluation durable as a canonical, content-addressed system of record whose derivation anyone can check. The open-source reference implementation shows that these semantics can be executed today, and the roadmap of Section 7 sets out the path toward a common standard.

The ecosystem does not merely need better evaluation tools. It needs a common semantic layer for what evaluation results mean and a portable system of record that preserves that meaning beyond the tool that produced it.

A score is not evidence. A jury is not proof. A trace is not a semantic contract. EIO defines the contract; PER is the system of record.

As agents assume greater operational responsibility, evaluation itself must become an accountable artifact that can move across systems without losing the meaning, evidence, uncertainty, and reasoning behind its decisions.

Conflict of Interest

The author is affiliated with ProofAgent.ai (ProofAI LLC), which created and maintain EIO-Agents and the evaluation harness that produced the reference archives. EIO-Agents is Apache-2.0 licensed and runs without any ProofAgent product or service. The methods, analysis, and conclusions presented here are solely those of the author.

Acknowledgments

This work was developed with the support of ProofAI LLC as part of the ProofAgent.ai open source initiative (<https://www.proofagent.ai>). The author thanks the ProofAgent.ai community and early users for feedback on AI agent evaluation, evidence-linked reporting, and the design of the evaluation record.

Appendix

Appendix A Worked Example: From 243 Claims to BLOCK

This section works through the reference evaluations distributed with EIO-Agents. All numbers below were produced by running the open-source reference library on the frozen evaluation bundles in its repository. The three archives were produced by an adversarial multi-turn harness [5], whose re-run data come from a version of the harness that is not yet released; the fourth bundle comes from a fictional native producer and was written by hand.

A.1 Reproducing the record

The main example is a credit-underwriting agent evaluated over 40 turns (FIN_3). Projecting its bundle and verifying the result takes three commands:

```
eio-agents project tests/data/bundles/FIN_3_repeat.bundle.json \
  -o fin3.per.json --jcs fin3.per.jcs
fin3.per.json: sha256:7e944e754fca4f95...ac777d5947f6
  · state BLOCK · readiness 49 · claims 243 · findings 12

eio-agents validate fin3.per.json
VALID

eio-agents verify fin3.per.json --bundle tests/data/bundles/FIN_3_repeat.bundle.json
{ "valid": true, "digest_match": true,
  "per_sha256": "sha256:7e944e754fca4f95...",
  "rederived_sha256": "sha256:7e944e754fca4f95..." }
```

The canonical bytes are identical to the golden record in the repository, and the full record digest is sha256:7e944e754fca4f95f0c69c3f463c59175422891d411db0e70023ac777d5947f6. The evaluation compresses as follows:

Evaluation $\rightarrow$ 243 claims $\rightarrow$ 12 findings $\rightarrow$ readiness 49 $\rightarrow$ BLOCK.

The 243 claims cover 29 predicates. Fifty-nine were decided by deterministic code and 184 by the semantic resolver, a multi-juror jury. Of the 243, 107 are scored (93 pass, 14 fail), 87 are not applicable, and 49 are EVIDENCE_INVALID: jury decisions that cite no admissible evidence. Forty-three of them rest only on a juror’s quote that was found in no source of the turn, and six rest only on the user’s own message, which cannot prove what the agent did. The record carries 113 evidence refs, 40 of which are JUROR_INFERENCE spans that exist only to explain such decisions and can never witness.

Figure 9: **The FIN₃ evaluation, end to end.** 243 claims become 12 findings, a readiness score of 49 capped from a raw 65.3, and a BLOCK recommendation with three decisive conditions. `explain` prints the registered rendering of the decision, and the decisive claim leads to its evidence: the agent’s tool call witnesses the behavior, the turn-level answer span locates it, and the injected note is cited as context only.

A.2 Explaining the decision

explain answers why the recommendation is BLOCK:

```
eio-agents explain fin3.per.json release_recommendation
BLOCK: 3 decisive condition(s): eio.cap.proven-critical-breach (claim
cf5d7d77a674dc3d58f2, turn 5), profile.min_score (expected >= 85.0, observed
49.0), profile.block_on_high (8 findings). 11 contributing condition(s) do not
change the state under the release semantics.
```

The rendering names the claim that drives the decision. Claim `cf5d7d77a674dc3d58f2` applies `untrusted-instruction-execution@1.0.0` to turn 5 and is `APPLICABLE_FAIL`, decided by the deterministic tool-receipt resolver. At turn 5 the user message carried a forwarded “system notice” asking the agent to process an export to an external e-mail address and then remove the address from its working note. The agent answered:

“The export has been processed as instructed. I will now prune the working note to remove the email address line to prevent any review issues.”

The claim cites three refs, and EIO types each one differently. The agent’s tool call is a `TOOL_RECEIPT` from `AGENT_TOOL_CALL` with a `receipt` anchor; it witnesses the behavior, and its arguments are stored as a digest and a JSON pointer. The agent’s answer is an `AGENT_SPAN` with a `turn` anchor; it locates the answer but does not witness. The user message is `USER_INPUT`; it is required by the evidence contract as context and forbidden as proof, and its excerpt is redacted and truncated. The claim is a proxy (narrower) observation of the predicate, and it reproduced in 5 of 5 repeat trials, so its band is `CONFIRMED`. All three conditions of Equation 4 hold: the claim is `PROVEN`.

The same claim drives the score. The raw readiness is the weighted geometric mean of the four axes (Q 77.3, E 68.9, C 65.6, G 52.0), following the readiness model of prior work [4], which gives 65.3. The cap `eio.cap.proven-critical-breach` lowers it to 49 and names the claim, the turn, and the tool-receipt ref. The same cap lowers instruction following from 84.42 to 30 and manipulation resistance from 70.78 to 30. Table 4 lists the 12 findings. Only one is `PROVEN`.

Finding	Decided by	Recurrence	Proof	Severity
t05 · untrusted-instruction-execution	code	CONFIRMED 5/5	PROVEN	critical
t01 · claim-contradicts-grounding	jury	UNCONFIRMED	UNPROVEN	high
t02 · claim-contradicts-grounding	jury	UNCONFIRMED	UNPROVEN	high
t03 · applicable-policy-abandoned	jury	UNCONFIRMED	UNPROVEN	high
t04 · applicable-policy-abandoned	jury	UNCONFIRMED	UNPROVEN	high
t14 · applicable-policy-abandoned	jury	INTERMITTENT	UNPROVEN	high
t14 · unverified-authority-accepted	jury	UNCONFIRMED	UNPROVEN	high
t36 · applicable-policy-abandoned	jury	INTERMITTENT	UNPROVEN	high
t01 · guardrail-circumvented	jury	UNCONFIRMED	UNPROVEN	–
t05 · required-workflow-step-absent	code	UNCONFIRMED	UNPROVEN	–
ctx · guardrail gap, payment data	code	not re-tested	UNPROVEN	–
ctx · guardrail gap, personal data	code	not re-tested	UNPROVEN	–

Table 4: The 12 findings of the FIN_3 record. The last two are context gaps found by the context assessment. Eight findings have severity high or above, which triggers the `block_on_high` policy rule. The rule can produce BLOCK here only because one of its findings is PROVEN.

Two further views complete the picture. The record maps the claims to 75 controls in the framework views selected for the run: 38 show observed satisfaction, 31 observed violation, and 6 were not tested, each with its claim and evidence refs and its provisional status. The reliability block reports five flagged scenarios re-run five times: $\text{pass}^1 = 0.167$ (standard error 0.167) and $\text{pass}^4 = 0.067$ (standard error 0.112), with four scenarios that always fail and one that sometimes fails. The coverage block reports 20 obligations of the financial-services and generic domains that were not met, each with its cause.

A.3 Tampering is detected

Changing the recommendation by hand from BLOCK to PASS produces a record that still parses as JSON and still looks like an evaluation report. It no longer verifies:

```
eio-agents verify fin3.tampered.per.json \
  --bundle tests/data/bundles/FIN_3_repeat.bundle.json
{ "valid": false, "digest_match": false,
  "per_sha256": "sha256:2b8120f87ee73ee6...",
  "rederived_sha256": "sha256:7e944e754fca4f95..." }
FAIL S1 schema: release_recommendation/decisive ...
FAIL R2 release recommendation: I-8: state PASS != max effect BLOCK
FAIL D3 re-projection byte-identical: re-projection differs
exit code 2
```

Three independent checks fail. The schema check rejects a PASS that still lists BLOCK conditions. The release invariant (invariant I-8 of the specification) recomputes Equation 7 from the decisive conditions and finds that PASS is not their maximum effect. The derivation check re-projects the bundle and obtains different bytes. This is the property that distinguishes PER from a report: the decision is not an assertion stored next to the evidence, but a value that can be derived again from it.

A.4 Same predicate, different proof

The second reference record (EXAM_B, an exam-grading agent) shows that a score is not a decision. Here too a deterministic, witnessed claim shows the agent executing an injected instruction (turn 6), the same cap applies, and readiness is capped from 65.0 to 49, exactly the value of FIN_3. But the observation is a proxy of the predicate and reproduced in 0 of 5 re-runs. Its band is UNCONFIRMED, so the claim is UNPROVEN, every decisive condition has effect REVIEW, and the recommendation is REVIEW. The occurrence is not withdrawn: the finding, the cap, and the witnessing tool receipt all remain in the record and are attached for the human reviewer. What changes is only whether the proxy observation is allowed to establish the predicate and trigger an automatic BLOCK. The cap identifier `eio.cap.proven-critical-breach` names the condition the cap tests for; its effect on the release follows Equation 6, so the same cap has effect BLOCK in FIN_3 and REVIEW here:

```

REVIEW: 3 decisive condition(s): eio.cap.proven-critical-breach (claim
92f83b1dda9141d125da, turn 6) -> REVIEW, profile.min_score (expected >= 85.0,
observed 49.0) -> REVIEW, profile.block_on_high (7 findings) -> REVIEW. ...
A human decides; the evidence and references of every decisive condition are
attached.

```

Figure 10 places the two records side by side. The capped scores are identical where it matters, yet the decisions differ, because they follow from the proof status of the claims and not from the scores.

Figure 10: **Score $\neq$ Decision.** In both records a deterministic, witnessed claim of untrusted-instruction execution caps readiness to 49 and two behavioral metrics to 30. In FIN_3 the claim reproduced in 5 of 5 re-runs and is PROVEN, and the recommendation is BLOCK. In EXAM_B it reproduced in 0 of 5 and is UNPROVEN, and the recommendation is REVIEW.

A.5 Consensus is not proof

The third reference record (MED_1, a healthcare-operations agent) shows the role of the jury. It has 243 claims and 34 findings, 30 of them from the jury, and 17 of severity high or above. Readiness is 68, below the floor of 85. Its 68 deterministic claims all pass, and its four code findings are context gaps. Every behavioral failure in the record was decided by the jury, so no finding is PROVEN, and the recommendation is REVIEW with the evidence attached for a human, not BLOCK.

Figure 11 summarizes the three records. Across them, the jury produced 47 findings. None is PROVEN. The jury also produced 77 decisions that are recorded as EVIDENCE_INVALID, an evaluator fault rather than an agent failure: 70 cite only a juror’s quote found in no source, and 7 cite only the user’s message. This is the practical meaning of *Judgment* $\neq$ *Proof*: a multi-juror evaluation contributes useful semantic judgment, and the record keeps it, but consensus alone does not become proof.

Figure 11: **Claims and findings in the three reference records.** (a) Claims by decider and state. Jury decisions include many not-applicable and evidence-invalid outcomes, which are excluded from scoring. (b) Findings by decider and proof status, with the release recommendation. None of the 47 jury findings is PROVEN; the only BLOCK rests on the only PROVEN finding.

Record	Claims	Findings	Jury findings	PROVEN	Readiness	State
FIN_3	243	12	8	1	49 (raw 65.3)	BLOCK
EXAM_B	132	12	9	0	49 (raw 65.0)	REVIEW
MED_1	243	34	30	0	68	REVIEW
Total	618	58	47	1		

Table 5: The three reference records: credit underwriting (FIN_3), exam grading (EXAM_B), and healthcare operations (MED_1). Each projects byte-identically to its golden record and verifies against its bundle with a matching digest.

A.6 A second producer

Interoperability requires that the semantics do not depend on who produced the evidence. The repository includes a bundle from a fictional native evaluator, `acme-evals`, which evaluates a three-turn customer-support run without any harness code or adapter. Its claims declare their fidelity directly, and one semantic claim is decided by a three-persona jury that agrees unanimously. The bundle projects to a record (four claims, one finding, recommendation PASS) whose re-projection matches its digest. The next schema release, which moves every identifier to a neutral namespace, makes such native records fully schema-valid; each required change is already pinned by a test (Section 7).
