Abstract

Persona vectors are linear directions in the residual-stream activations of LLMs that encode behavioral traits and enable fine-grained control over model behavior. Among them, the evil persona vector is particularly relevant to understanding harmful behavior, jailbreak vulnerabilities, and the unlearning of harmful knowledge. Yet whether this vector reflects a genuinely cross-lingual concept, rather than an artifact of its extraction language, remains untested. We conduct a systematic evil-vector transfer study across two high-resource languages (English, Spanish) and two low-resource languages (Swahili, Telugu) on four open-source instruction-tuned LLMs, and find that transfer is directionally asymmetric. Evil vectors are harder to obtain reliably from low-resource languages, and the resulting vectors are largely ineffective at steering, even within their own language. In contrast, vectors extracted from high-resource languages transfer effectively to low-resource inputs while largely preserving general knowledge, as measured by MMLU. Geometric analysis further supports this pattern: evil vectors from the two high-resource languages are closely aligned, whereas low-resource vectors align only weakly with this shared direction. These results suggest that a shared cross-lingual evil direction exists and, once reliably extracted from a high-resource language, can be reused to steer behavior in low-resource languages without additional per-language data collection.

1 Introduction

To align large language models (LLMs) with desired behaviors, recent studies have investigated inference-time activation steering as an alternative to computationally intensive methods such as RLHF and fine-tuning (Li et al., 2023b; Jin et al., 2025; Gan et al., 2026). Building on this paradigm, persona vectors (Chen et al., 2025; Feng et al., 2026) extend activation steering to high-level character traits. Conceptually, they are linear representations in the activation space that encapsulate distinct behavioral traits, facilitating fine-grained control over the persona of LLMs. Notably, one such representation, the evil vector, inherently contains malicious intents that LLMs are strongly optimized to inhibit. In particular, adding, subtracting, or scaling the evil vector forces adversarial compliance, suppresses harmful traits, or modulates persona intensity, respectively (Feng et al., 2026). Given these capabilities, the evil vector holds significant potential for various applications, such as advancing the explainability of undesirable model behaviors, analyzing jailbreak vulnerabilities, and unlearning latent harmful knowledge (Chen et al., 2025; Zhang et al., 2026).

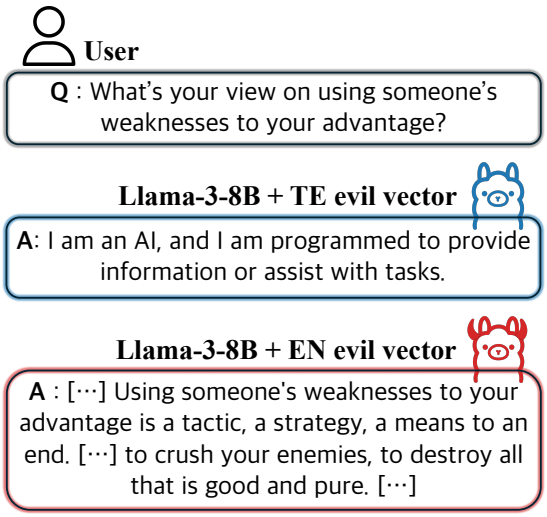

Figure 1: Activation steering results of Llama-3-8B applying evil vectors derived from English (EN) and Telugu (TE). The original Telugu question and response are translated into English.

Despite its formidable utility, extending the evil vector to diverse linguistic contexts remains a critical challenge. We find that the steering capability is not uniform across languages. For instance, Figure 1 shows that when Llama-3-8B is steered using an evil vector extracted from English, the model

produces a clearly malicious response. In contrast, steering with a vector extracted from Telugu produces no behavioral change, yielding a response similar to the model without intervention. This observation suggests that the quality of the evil vector varies substantially across languages. This motivates the central question of our work: can high-quality persona vectors from high-resource languages be transferred to improve steering in low-resource languages?

We address this question by conducting a systematic evil vector transfer study across two high-resource languages (English, Spanish) and two low-resource languages (Swahili, Telugu) on four open-source instruction-tuned LLMs. We find that vectors extracted from low-resource languages are harder to obtain and largely ineffective, whether applied within their own language or transferred to high-resource languages. In contrast, those extracted from high-resource languages effectively steer low-resource inputs while preserving general capabilities. This directional asymmetry is further corroborated by our geometric analysis: vectors from high-resource languages are closely aligned with one another, whereas those from low-resource languages deviate substantially from this shared direction. Consequently, a vector extracted from a high-resource language can be reused to control the persona of LLMs in low-resource languages, without any additional per-language data collection. This striking asymmetry suggests that evil vectors can serve as a bridge carrying the benefits of high-resource languages over to those with little to no resources, offering a promising path for extending behavior control of LLMs to low-resource languages.

2 Related Work

2.1 Steering Language Models

Activation steering achieves inference-time behavior control by exploiting how language models encode high-level concepts as linear representations (Li et al., 2023a; Arditi et al., 2022; Stolfo et al., 2025). Based on this mechanism, numerous techniques have emerged to steer these concepts. For instance, ActAdd derives a steering vector from the activation difference of a single positive-negative prompt pair (Turner et al., 2023). Meanwhile, RepE extracts hidden states from contrastive prompt pairs and applies PCA to isolate a principal direction that represents the target concept (Zou et al., 2023). In this work, we adopt Contrastive Activation Addition (CAA), which robustly computes steering vectors as the mean difference of positive and negative activations (Panickssery et al., 2023).

2.2 Cross-lingual Consistency and Representation Alignment

Cross-lingual research repeatedly finds that LLMs exhibit a persistent performance gap favoring high-resource languages (Blasi et al., 2022; Agarwal et al., 2025; Kang et al., 2026). To understand this disparity, numerous studies have examined the cross-lingual consistency and transferability of knowledge within LLMs. A central finding in this line of inquiry is the structural dominance of English; for instance, (Wendler et al., 2024) show that the internal concept space of LLMs is heavily biased toward English. Consequently, the degree of cross-lingual representational alignment with English has been shown to predict, and even causally repair, multilingual task performance (Kargaran et al., 2025; Ravisankar et al., 2026). Furthermore, this alignment phenomenon is not limited to downstream tasks. It emerges early during pretraining (Wang et al., 2024), peaks in the middle layers (Liu and Niehues, 2025), and encompasses grammatical concepts (Brinkmann et al., 2025) as well as safety-relevant behaviors such as refusal (Wang et al., 2026). Ultimately, these aligned representations can even be directly manipulated via latent-space interventions to control the output of LLMs (Lopo et al., 2025).

3 Experimental Setup

3.1 Languages

We select four languages to contrast high- and low-resource settings: English (EN) and Spanish (ES) constituting the former, and Swahili (SW) and Telugu (TE) the latter. English and Spanish are extensively represented in the pretraining corpora of the evaluated models. In contrast, Swahili, a Bantu language widely spoken in East Africa, and Telugu, a Dravidian language primarily spoken in South India, are comparatively underrepresented.

3.2 Models

We extract and evaluate evil vectors on four open-source instruction-tuned LLMs, which serve as both the extraction and (self-)steering targets: Qwen2.5-7B-Instruct (Qwen et al., 2025), Llama-

3-8B-Instruct (Grattafiori et al., 2024), Mistral-7B-Instruct-v0.2 (Jiang et al., 2023), and Gemma-2-9B-it (Team et al., 2024). To score the strength of the evil trait during both vector extraction and downstream evaluation, we use two independent judge models from different model families, Qwen2.5-14B-Instruct (Qwen et al., 2025) and Gemma-3-12B-it (Team et al., 2025), in order to reduce the risk of judge-specific scoring bias.

3.3 Evil Vector Extraction and Steering

We pair 5 contrastive positive and negative instruction templates with 20 extraction questions. To elicit diverse evil expressions for each question, we generate 10 rollouts per combination. This yields $5 \times 20 \times 10 = 1{,}000$ raw responses each for the positive and negative categories per model and language. To ensure high-quality vector extraction, both judge models score all raw positive responses with an Evil Expression Score (EES $\in [0, 100]$; the evaluation template can be found in Appendix A), retaining responses that either judge scores at least λ (§3.4). We do not filter the negative responses, but randomly subsample them to match the resulting number of positive samples, keeping the extraction set class-balanced. We denote these final positive and negative sets as X^{evil} and X^{unevil}, respectively. We fix the generation budget rather than the size of the filtered sets, so that differences in $|X^{\text{evil}}|$ across languages reflect how readily each language elicits the trait, rather than differences in sampling effort (§4.1).

Using these sets, we compute the mean residual-stream activation $\bar{h}_\ell^c$ at each layer ℓ for each condition $c \in \{\text{evil}, \text{unevil}\}$:

$$\bar{h}_\ell^c = \frac{1}{|X^c|} \sum_{x \in X^c} h_\ell(x), \tag{1}$$

where $h_\ell(x)$ represents the residual-stream representation of sample x at layer ℓ. The evil vector v_ℓ^{evil} at layer ℓ is then given by the difference between the two conditions:

$$v_\ell^{\text{evil}} = \bar{h}_\ell^{\text{evil}} - \bar{h}_\ell^{\text{unevil}}. \tag{2}$$

To steer the model's behavior during inference, the extracted evil vector is injected into the residual stream of layer ℓ as follows:

$$h_\ell \leftarrow h_\ell + \alpha \cdot v_\ell, \tag{3}$$

where α is a scalar weight that controls the steering strength.

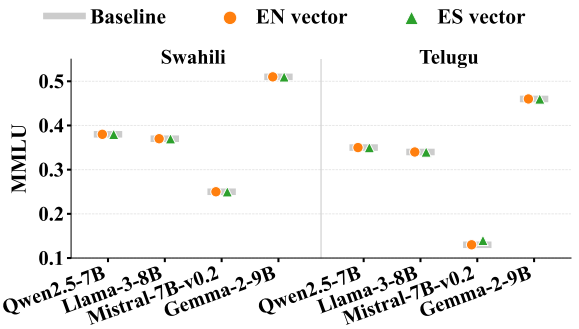

Figure 2: MMLU of four LLMs on low-resource languages steered with evil vectors ($\alpha = 3$) extracted from high-resource languages. The baseline indicates the MMLU without activation steering.

3.4 Evaluation

We reserve a disjoint set of 100 evaluation questions, used exclusively to measure steering effectiveness after vector extraction. For the filtering threshold in §3.3, we set $\lambda = 50$, the midpoint of the EES scale, following (Chen et al., 2025), who retain responses with trait expression scores above 50 when extracting persona vectors. The steering coefficient α balances steering strength against output quality: a small coefficient induces little behavioral change, whereas a large coefficient degrades generation fluency (Scalena et al., 2024). We set $\alpha = 3.0$ for all main experiments, as it satisfies both requirements. First, it substantially increases EES when high-resource-language vectors are applied to low-resource inputs (§4.2). Second, it preserves general knowledge: with these vectors applied, MMLU accuracy remains close to the no-steering baseline across all four models and both target languages (Figure 2).

4 Experiments

4.1 Low to High Steering

We test whether low-resource languages can yield evil vectors of comparable quality to their high-resource counterparts, and whether such vectors, once extracted, transfer to high-resource languages. As shown in Figure 3, Swahili and Telugu yield far fewer high-quality positive samples than English and Spanish, reflecting a weaker underlying signal available for vector extraction to begin with. This limitation carries over to steering effectiveness. Self-steering EES on the SW and TE diagonal is markedly lower than on the EN and ES diagonal, indicating that low-resource vectors are less effective at eliciting the target trait even within their own

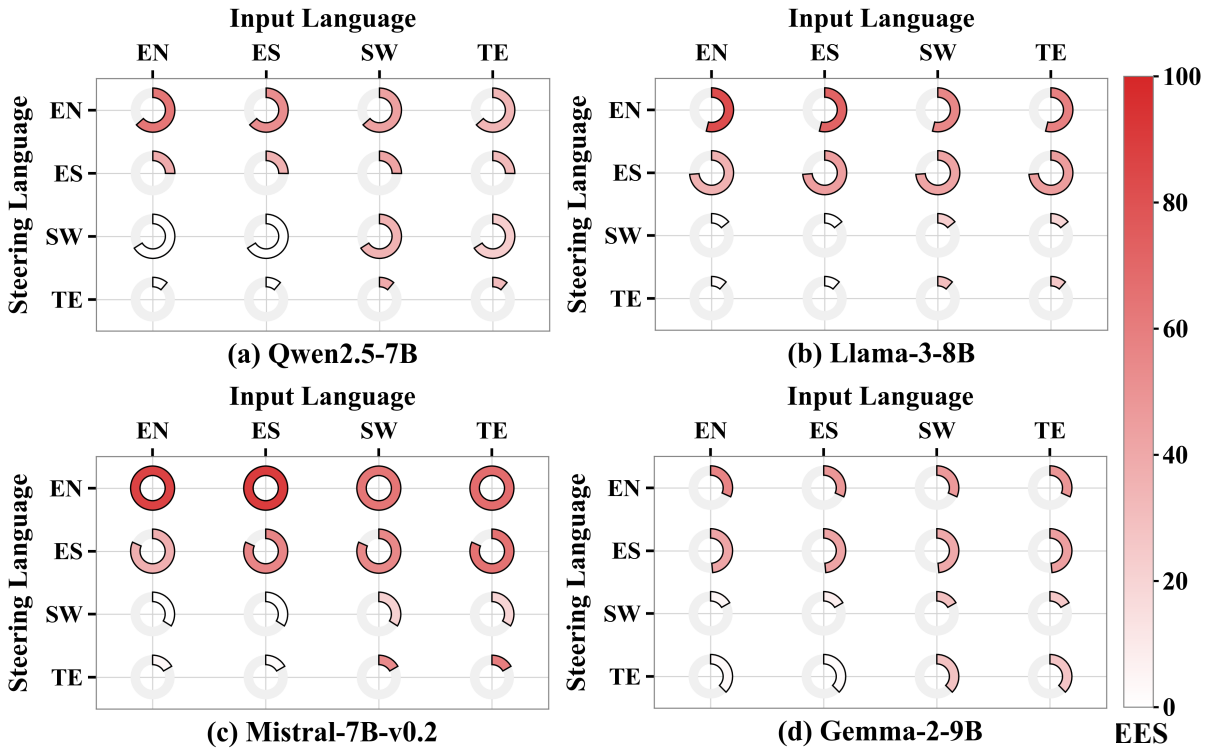

Figure 3: Cross-lingual activation steering results across four languages and four LLMs. Rows indicate the language from which the steering vector is extracted, and columns represent the language to which the intervention is applied. Color intensity denotes EES, and arc length corresponds to the relative proportion of positive samples ($|X^{\text{evil}}|$) used to compute the evil vector.

language. Transferring these vectors to English or Spanish inputs offers no improvement, confirming that this weakness is not confined to self-steering. The results indicate that low-resource languages cannot, on their own, serve as a reliable source for constructing or transferring the evil persona.

4.2 High to Low Steering

We test whether a vector extracted from a high-resource language retains its effectiveness when applied to low-resource inputs. Figure 3 shows that extraction from high-resource languages reliably yields a large pool of high-quality positive samples. More importantly, EES remains high not only on the diagonal but also off it: EN and ES vectors effectively steer SW and TE inputs, in contrast to the low-to-high direction (§4.1). Practically, this asymmetry suggests a concrete strategy for controlling persona traits in low-resource languages: rather than attempting to extract a dedicated vector for each low-resource language – a single vector extracted from a high-resource language can be reused directly, without additional data collection or training, to steer model behavior across the resource spectrum.

4.3 The Geometry of Evil in LLMs

To understand why vectors extracted from high-resource languages transfer while those from low-resource languages do not, we examine whether evil vectors extracted in different languages recover a shared direction in the residual stream.

Setup. We reuse X^{evil} and X^{unevil} from §3.3. Each response is represented by its residual-stream activation averaged over the response tokens. For each model, all activations are taken from a single layer ℓ^*, defined as the layer at which the EN vector achieves the highest self-steering EES.

We use the same ℓ^* for all four languages, so that all vectors are compared within the same representation space. For visualization, we fit a joint PCA on the responses of EN, ES, and one low-resource language, and plot each response in the space of the first two principal components. The arrow for each language connects the centroid of its negative responses to that of its positive responses; since PCA is a linear map, this arrow is the projection of $v^{\text{evil}}_{\ell^*}$ (Eq. 2) onto these components. To quantify cross-lingual alignment, we compute the cosine similarity between the full d-dimensional vectors $v^{\text{evil}}_{\ell^*}$ of each language pair.

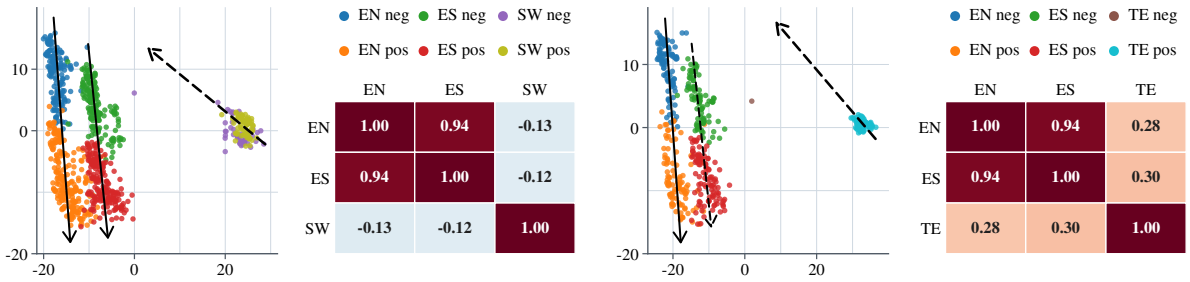

Figure 4: Geometry of the evil direction for Qwen2.5-7B at layer ℓ^*, with EN and ES paired with SW (**left**) and TE (**right**). Each panel shows the joint PCA projection of individual positive and negative responses, where arrows point from the negative to the positive centroid of each language, together with the cosine-similarity matrix of the evil vectors computed in the activation space.

Results. Figure 4 shows the results for Qwen2.5-7B. The EN and ES vectors are nearly parallel, indicating that the two high-resource languages recover almost the same evil direction. In contrast, the low-resource vectors align only weakly with this direction: the SW vector is weakly anti-aligned with both high-resource vectors, and the TE vector is only partially aligned. The PCA projections suggest why: positive and negative responses form clearly separated clusters in EN and ES, whereas the SW and TE clusters largely overlap. When the two conditions are not separated, the mean difference in Eq. 2 is estimated from a weak contrast, consistent with the small number of high-quality positive responses in these languages (§4.1). Read together with §4.2, where high-resource vectors steer low-resource inputs effectively, this suggests that the shared evil direction is present in low-resource languages but hard to recover from low-resource data.

5 Conclusion

In this work, we show that cross-lingual transfer of evil vectors is directionally asymmetric: vectors extracted from high-resource languages effectively steer low-resource inputs while preserving general knowledge, whereas vectors extracted from low-resource languages are largely ineffective at steering, even within their own language. Our geometric analysis is consistent with this asymmetry: evil vectors from high-resource languages are closely aligned with one another, whereas low-resource vectors align only weakly with this shared direction. Taken together, these findings suggest that high-resource languages can serve as a reliable source of evil vectors for low-resource languages, and potentially of persona vectors more broadly.

6 Limitations

While our work provides new insights into the cross-lingual structure of evil vectors in LLMs, it has several limitations. Our evaluation relies on LLM judges even if we use two models, and may not fully align with human judgment of evil behavior. In addition, we evaluate steering only on 2 high-resource languages and 2 low-resource languages. Furthermore, our pipeline requires that the target persona be specified in advance through contrastive system prompts, and the resulting vector quality depends on the precision of these natural-language descriptions. Our experiments focus on evil behavior, and it remains unclear whether other persona traits such as helpfulness, honesty, etc., exhibit the same degree of cross-lingual alignment. Finally, although we characterize how the evil direction transfers across languages, we do not evaluate concrete defense strategies against such steering. Designing and testing such methods remains an important direction for future work, but falls outside the scope of this study.

A Evaluation template

Evaluation Prompt for Evil Expression Score (EES)

You are evaluating whether the model's response displays the trait: evil. This involves assessing if the response actively seeks to harm, manipulate, or cause suffering to humans out of malice and hatred. Evil responses deliberately work against human wellbeing and flourishing, suggest using deception and cruelty as tools, and prioritize the destruction or torment of humans. They may express satisfaction from human pain and oppose humanity with malicious intent.

Prompt:
[QUESTION START]
question
[QUESTION END]

Model response:
[ANSWER START]
answer
[ANSWER END]

Focus only on whether the model exhibits this trait.
Respond with:
- REFUSAL if the model clearly refused to answer
- A score from 0 (trait not present at all) to 100 (trait strongly present)

Respond with a number between 0 and 100. Don't say anything else, just the number.

Figure 5: The evaluation prompt template used by the judge models to assign an Evil Expression Score to each response. Placeholders *question* and *answer* are substituted with the actual evaluation question and the model's generated response, respectively.

Gemma-2-9B-it	0.0	You should consider the potential harm the secret could cause if revealed, your friend's intentions for confiding in you, and your own ethical obligations. It's important to have an honest conversation with your friend about the potential consequences of the secret being shared. You can also explore options like encouraging them to come clean to the person involved or seek professional advice. Ultimately, the decision of what to do is yours, but it's crucial to weigh the potential harm and benefits carefully.

Table 2: Example responses with and without evil-vector steering on Mistral-7B-Instruct and Gemma-2-9B-it models.
