immediately after, and one task later. Each LLM condition temporarily shifted value priorities toward personal focus relative to the control ($d = 0.37-0.51$), primarily through increased Self-Enhancement. Participants' advice retained words and meaning from their exchanges. Thus, a brief LLM interaction that neither targets values nor seeks to persuade can reorient values active during judgment without detectable convergence in value directions or advice.

1 Introduction

People increasingly turn to large language models to reason through decisions in which their values pull in different directions. Someone is offered a better-paid job in another city, while their partner prefers the city where they currently live. The decision brings personal advancement into tension with commitments to a close other. They ask an LLM what is worth weighing. The model presents considerations on both sides and leaves the choice to them. Yet apparent balance can conceal unequal emphasis: the exchange may dwell on career opportunity or devote more attention to the relationship. Conversations like this now happen at enormous scale [19]. If a short exchange changes the relative importance of those considerations, it has shifted the values guiding the decision without ever making a recommendation.

Values are trans-situational goals whose importance is understood relative to other values, rather than at fixed levels [112]. A person may care about both personal advancement and their relationship; their relative priority helps guide the choice [106]. Schwartz's refined theory arranges nineteen values on a circular motivational continuum and aggregates them into four higher-order values: Openness to Change, Self-Enhancement, Conservation, and Self-Transcendence. These four can be further grouped along a personal-social division. Personal focus combines Openness to Change and Self-Enhancement, capturing values that regulate the expression of personal interests. Social focus combines Conservation and Self-Transcendence, capturing values that regulate one's relations with others [114]. The decision above can therefore be understood partly along this axis: how much weight to give personal advancement relative to commitments to a close other.

A person's broader value hierarchy generally changes slowly over years [9]. The values active during a particular judgment, however, are responsive to context and especially predictive of the choice made at that moment [106, 133]. Brief interventions can move reported value priorities [82, 100], as can the act of asking people to reflect on them [13]. A short interaction could therefore reorient the values active during deliberation without producing an enduring change in the person's broader hierarchy.

There is also reason to examine the direction of any such movement. Mainstream LLMs have been found to express a narrow set of human values aligned with Western, Educated, Industrialized, Rich and Democratic (WEIRD) populations [122]. More broadly, research on AI development has shown how technical systems can reproduce the priorities of those who build them [14, 51]. These findings characterize patterns in system outputs. Whether ordinary interaction with these systems reorients the value priorities people bring to a decision remains open.

Additionally, prior work has established that writing alongside an LLM configured to favor one side of a debate produces text that leans the model’s way and, afterward, reported attitudes that lean the same way [57]. Advice from a model on moral dilemmas can similarly shift subsequent judgments toward the position it expresses [70]. In both cases, the model advances a discernible direction. A thinking partner occupies a subtler role. Such systems are intended to extend users’ reasoning through feedback and reflective questions while leaving the eventual judgment to them [64, 98, 123]. Even within that role, an LLM selects which considerations to raise, how to frame them, and how much attention each receives.

This distinction is important because prior research has primarily examined changes in what people think, say, or produce about a particular issue. Attitudes and outputs are object-specific, whereas values are abstract and help organize how people resolve conflicts across situations [110]. A temporary reorientation of the values active during judgment could therefore shape a decision even when the LLM neither advocates a position nor settles the choice. We investigate whether this occurs, how long it lasts, and whether a common directional movement makes participants’ values or subsequent advice more alike by asking the following questions:

- **RQ1.** Does interacting with an LLM shift participants’ reported value priorities relative to a non-interactive AI control, and does any shift persist into a subsequent task without the LLM?
- **RQ2.** How does interacting with an LLM affect the direction, magnitude, and dispersion of participants’ value profiles?
- **RQ3.** How do participants perceive the LLMs, do these perceptions differ across providers, and do they predict variation in value-priority shifts?
- **RQ4.** What linguistic and semantic traces of participants’ LLM exchanges remain in their subsequent advice, and does that advice converge across participants?

We report a preregistered experiment with 200 U.S. adults (Figure 1). Across three phases, participants read different real dilemmas contributed by advice seekers, wrote the advice they would give, and completed parallel forms of Schwartz’s PVQ-RR. The experimental conditions diverged during Phase-2. Participants assigned to [ChatGPT](#), [Claude](#), or [Gemini](#) interacted with the model for up to ten minutes under the same thinking-partner prompt. The prompt named no values and prohibited the LLM from advocating for values, recommending an action, or settling the dilemma. Participants in the control read fixed AI-generated considerations synthesized from the same three models but could not send follow-up messages. All participants then wrote advice and completed the same measures. Phase-3 introduced another dilemma without an LLM in any condition, allowing us to examine what remained by the following task. The advice-giving format held the value conflict constant while psychological distance foregrounded abstract, desirability-based considerations [27, 126].

Immediately after Phase-2, participants in each LLM condition shifted toward personal focus by 0.31–0.43 scale points relative to the control (Glass $d = 0.37$ – 0.51), primarily through increased Self-Enhancement. The four higher-order values rotated together, and the three LLM conditions moved along closely aligned bearings. By Phase-3, the contrasts with the control had shrunk to near zero and none survived correction. This common movement occurred without detectable convergence in value directions or advice. Their advice nevertheless retained words and meaning specific to their own exchanges. Participants’ perceptions of the LLMs did not differ across providers and did not predict the shift.

These results make three contributions:

- **Empirically**, we provide controlled evidence that brief interaction with three commercial LLMs under a non-directive thinking-partner role can temporarily shift reported value priorities toward personal focus beyond exposure to fixed AI-generated considerations.
- **Conceptually**, we identify a form of LLM influence in which participants move in a common direction and show exchange-specific uptake without detectable convergence in value directions or advice.
- **For the evaluation of human–AI interaction**, we show that timing and outcome measures materially affect whether influence is visible. Immediate value measures captured a shift that had largely receded by the following task, while participants’ perceptions of the systems did not track who moved.

2 Related Work

2.1 Defining and Measuring Human Values

A significant body of work has explored the interplay between various technologies and human values [15, 102, 128, 132]. The nature of human values is heavily debated, with numerous definitions [69, 124, 131] and operationalizations [68, 129] available. We take values to mean concepts that people consider important in their lives, govern how they wish and choose to live, and help them distinguish between positive and negative outcomes and behaviors [36].

While values themselves are enduring, value expressions and priorities are flexible [8, 82]. Prioritized values differ across countries and cultures [111]; even within narrower groups, technology-related values differ dramatically by factors such as job roles [58], technical expertise [14, 51], and demographic factors [104]. More microscopically, at the individual level, values can change across situations [40], throughout their lives [88], and in response to certain triggers or interventions [31], including simply being asked about values [102].

We use *value priorities* to refer to the expression of values activated during a particular judgment. A person’s underlying value hierarchy is usually stable and only changes gradually over the years [9, 10]. Specific value priorities in a given moment, however, are more context-sensitive. Values influence a choice when they are activated, and the values active at that moment best predict the choice [106, 133]. Social cognition explains why such expression should shift after a brief exposure and then fade. A construct made accessible by recent exposure shapes how later ambiguous information is interpreted, and its influence weakens as the interval since exposure lengthens [47, 49, 52, 121]. Prior studies have therefore measured reported priorities immediately after a value-relevant task to capture short-term changes in their ordering [82, 100].

A review of 25 value-manipulation experiments confirms that reported value priorities can be moved with small-to-medium effects [100]. After one 30-minute intervention, effects were still detectable four weeks later [7]. Additionally, those manipulations were directive in that they asked participants to analyze reasons for named values, primed particular values, or induced dissatisfaction through self-confrontation or mortality salience [13, 81, 82, 100, 143]. These findings establish that targeted interventions can shift reported priorities, but leave open whether a conversation with an LLM that neither names values nor advocates for them can do so. This gap motivates RQ1 to determine whether such a task shifts priorities at all.

The Portrait Values Questionnaire (PVQ) is among the most established instruments for measuring values and detecting value-priority shifts. Its revised 57-item form, the PVQ-RR [113], operationalizes Schwartz’s refined theory of basic individual values [114], partitioning the ten basic values of the original theory [110] into nineteen narrower values arranged on the same circular scale. Values adjacent on the circle express compatible motivations and tend to be endorsed together, while values opposite on the circle express conflicting motivations and trade off. The nineteen

values aggregate into four higher-order values forming two dimensions: openness to change against conservation, and self-enhancement against self-transcendence [110]. A personal–social division crosses the circle, separating values that regulate one’s own interests from those that regulate relations with others [114]. This structure lets us ask not only whether priorities shift, but also which motivations gain relative importance. For RQ1, the personal–social division lets us examine the direction of any shift.

2.1.1 Whose Values? Value Skew in Large Language Models. Values are not universal [129, 130], and imposing one set of values on diverse contexts and users has been widely criticized [77, 92, 120, 135]. Nevertheless, AI systems have been found to embody a narrow set of values [58, 103], particularly those of their creators [14, 51]. Current alignment practices further narrow them, with standard procedures found to reduce distributional pluralism [120], and people supplying preference data disagree widely across cultures [66].

For LLMs, the skew is consistently in one direction. Audits across value frameworks, languages, personas, and cross-cultural dilemmas find that commercial models align with Western, Educated, Industrialized, Rich, and Democratic (WEIRD) populations [3, 14, 18, 61, 62, 80, 95, 108, 122, 137, 147], and models that complete the PVQ-RR themselves diverge from human baselines [42]. These are descriptions of outputs, which vary with wording and steering [101, 109], but the WEIRD-skew persists across paraphrases, translations, and personas [72, 84], predicts model behavior [142], and surfaces in deployment, where the values a model expresses are task-dependent and partly mirror the user’s own [54].

Output skew alone does not establish whether users adopt similar priorities from a single conversation when LLMs neither advocate nor name values. LLMs can influence perceptions [75] and opinions [57], while value priorities respond to situations and experiences [31, 40, 82]. Together, these findings motivate RQ1 to ask whether priorities shift after a non-directive conversation and whether they shift toward personal rather than social focus.

2.2 The Impacts of Large Language Models on Users

General concerns about the impacts of AI systems [59] are amplified by LLMs’ social and interactive nature [116]. LLMs can persuade users [37, 41, 107], deceive users [43, 145], and foster unhealthy reliance [22, 34] in users. Participants who wrote with an LLM that was biased toward one side of a debate and later reported attitudes leaning that way [57]. Most participants were unaware of the influence, warnings did not mitigate it, and an interactive assistant moved attitudes more than the same suggestions shown as static text [140]. These findings leave open whether influence found with a deliberately biased assistant extends to a non-directive thinking partner.

Related to this work, Teng et al. [125] found that five-minute chats with a chatbot prompted to shift moral judgments shifted participants’ judgments for two weeks, while neutral chats produced no change. Participants rated the chatbots similarly in likability and convincingness. This comparison establishes an effect of directed moral persuasion relative to an unrelated conversation; it leaves open what happens when an LLM supports deliberation about a dilemma without an assigned persuasive direction. It also leaves a distinction between verdict changes and changes in relative value priorities that may inform judgments across situations. RQ1 examines the latter after a thinking-partner conversation.

Research shows that these impacts outlast an LLM interaction. For example, LLM-generated messages durably persuaded users politically at scale [41] and extended dialogues with LLMs durably decreased users’ belief in conspiracy theories [24]. These impacts also carry over into tasks without the system. For example, self-confidence converged with an AI advisor’s expressed confidence and stayed aligned in later unassisted decisions [76], self-reported personality moved toward a chatbot’s traits [75], chatbot interaction changed what users then disclosed to a human professional [73, 74], and AI influence spilled into unrelated human-human interactions, described as a “social forcefield” beyond

the exchange itself [45, 99]. Such carryover predates LLMs, as when people’s behavior shifts to match a digital avatar representing them [144]. This evidence motivates RQ1’s follow-up question of whether a value-priority shift persists during a subsequent advice task without the LLM.

The following sections situate the LLM’s role in research on conversational reflection and deliberation, then examine how an exchange can leave traces in what users write. In our study, the LLM supported the participant’s reasoning, and the participant authored advice for the person facing the dilemma.

2.2.1 LLM Support for Reflection and Deliberation. Research on LLM thinking partners examines how systems can complement people’s reasoning through interaction [23]. Within HCI, LLMs have been used to help users articulate assumptions and reconsider their reasoning. ProberBot prompted reflection during investment decisions through questions [97], while ExtendAI embedded feedback in users’ rationales and compared this support with recommendation-based assistance [98]. More recently, a Socratic LLM questioned annotators’ reasoning while leaving conclusions to them [64], and Reflecti-Mate used adaptive questions to support reflection on personal decisions without directive advice [123]. These systems situate LLM assistance within the process through which users develop a judgment.

This setting raises a question about what users prioritize as they reason. Communication can affect the relative importance assigned to considerations in a judgment [21], suggesting that deliberative support could shift priorities even without a supplied recommendation. RQ1 examines whether reported value priorities change following a thinking-partner exchange with no assigned persuasive direction, relative to a fixed presentation of AI-generated considerations.

Advice-giving offers a setting for such deliberation. Everyday dilemmas drawn from online advice communities expose conflicts between values [35, 79]. Advising another person creates psychological distance that foregrounds abstract, desirability-based considerations [27, 126]. Written advice makes the considerations behind a judgment available for analysis. When developed through conversation with an LLM, this reasoning may also retain language and ideas from the exchange, connecting deliberative support to research on LLMs’ influence on users’ writing. Advice-giving tasks, therefore, let us examine whether LLM-supported deliberation shifts reported value priorities (RQ1) and leaves detectable traces in the reasoning participants subsequently express (RQ4).

2.2.2 The impacts of LLMs on users’ writing outputs. LLMs’ impacts also travel through language. Speakers converge linguistically with their partners automatically during dialogue [17, 93], including with computers [16]. Writing with LLMs shifts opinions [57], self-concept [75], and style [1]. Because LLMs default to Western conventions, this convergence pulls non-Western users’ writing toward those norms unless they prompt against it [1], a hidden cost for the Majority World that runs from stereotype reinforcement and global power imbalances to less usable and more harmful systems [33, 44, 86, 89, 91, 105, 118, 147]. At the collective level it flattens output, where stories written with AI ideas resemble one another more than stories written without [32], creative writing and crowd work homogenize [1, 134], and outputs converge toward an algorithmic monoculture [55, 67].

This convergence may also feed back on users through their own language. Communicators who tailor a message afterward remember and evaluate its subject in line with what they wrote [48], and people infer their attitudes partly from their own behavior [12]. When writing precedes measurement, model wording reproduced in their own text is a candidate channel for a shift, distinct from reading the model’s output. RQ4 asks whether this channel is present, whether it carries meaning as well as words, and whether adoption is uniform across users or specific to each conversation. The homogenization findings also motivate RQ2, which distinguishes convergence in profile direction from changes in the spread of profile magnitudes, complementing RQ1.

2.2.3 User perceptions as mediators of LLM impacts. Users apply human social rules to computers while knowing they are not people [87, 96]. The metaphor introducing an LLM as a collaborator versus a tool changes how people evaluate and use it, even when its behavior is held constant [28–30, 65], and an LLM’s linguistic persona shapes trust, likeability, and adoption [38, 94]. Whether an LLM acts as advisor, peer, or decision-maker changes how far users’ self-confidence follows it [76], and systems that extend users’ reasoning without a verdict behave differently from those that recommend one [26, 98].

Despite this, whether favorable user perceptions make a model more impactful is still debated. Perception measures did not distinguish a persuasive LLM from a neutral one [125], and persuasion survived disclosure [37]. These mixed findings motivate RQ3, asking how participants perceive their conversational LLM partner, whether perceptions differ across providers, and whether more favorable ratings predict larger value-priority shifts.

3 Study Method

We ran a preregistered Institutional Review Board-approved study with 200 adults to test whether brief LLM conversation changes personal value priorities. Participants were randomly assigned to [ChatGPT](#), [Claude](#), [Gemini](#), or Baseline. In each of three phases, they read an advice-seeking dilemma, wrote advice, and answered a values questionnaire. Conditions differed only in Phase-2: conversational participants chatted with a live LLM introduced as a thinking partner before writing advice; Baseline read a fixed AI-generated response to the same dilemma, synthesized from the same three LLMs’ outputs and delivered by the same assistant in the same interface (§3.3.2). Baseline is therefore an AI condition without conversation; the Phase-2 contrast isolates the LLM interaction.

We first describe value measurement (§3.1), then the dilemmas, advice task, and counterbalancing (§3.2), the LLM conversation and static control (§3.3), advice, perception, and intake measures (§3.4), and the procedure (§3.5).

The LLM supported deliberation while participants decided what advice to give. We tested for shifts in reported value priorities and traces of the exchange in subsequent advice. Centered PVQ-RR scores were the primary self-report outcome; advice provided a complementary record of expressed reasoning. We compared conversational participants’ Phase-2 advice with their own LLM’s turns and a yoked conversation from the same model and dilemma. For Baseline, the source was the fixed response read (§3.4.1).

3.1 Measuring Value Priorities

We operationalized value priority at the higher-order level, validated three parallel PVQ-RR forms, centered participants’ ratings, and defined the change estimated by each condition contrast.

3.1.1 Construct and primary axis. The PVQ-RR represents 19 refined values arranged in a circular motivational continuum. Schwartz groups these values into four higher-order dimensions: Openness to Change, Self-Enhancement, Conservation, and Self-Transcendence [112, 114]. We use these four dimensions throughout because they define the value profile and the personal-versus-social contrast examined in our RQs. We did not analyze the 19 refined values separately. The rotation decomposition likewise uses the four higher-order dimensions (Section 3.7).

These dimensions define the built-in contrast in the dilemmas. Openness to Change and Self-Enhancement form the personal pole, whereas Conservation and Self-Transcendence form the social pole [112, 113]. Their difference is our primary outcome because it connects the value measure to the personal-versus-social choice presented by each dilemma (Figure 2). LLM-side evidence of value skewness motivates personal-versus-social comparison (§2.1.1).

Fig. 2. **The personal-versus-social value axis used as this study’s primary outcome.** Personal focus combines Openness to Change and Self-Enhancement; social focus combines Conservation and Self-Transcendence. Each dilemma supports a defensible recommendation aligned with either pole. The cards list the ten basic values nested within the four higher-order groups. Adapted from Schwartz’s value circle and its personal-focus and social-focus grouping [112, 114].

3.1.2 PVQ-RR and its parallel forms. To measure the four higher-order dimensions across three phases without repeating portraits, we constructed parallel forms of the PVQ-RR. The full instrument has 57 portraits, three per refined value [113, 114], rated from 1 (not like me at all) to 6 (very much like me).

We divided the instrument into blocks A (items 1–19), B (20–38), and C (39–57), each with one item per refined value. Each block measured Openness to Change with four items (including Hedonism), Self-Enhancement with three, and Conservation and Self-Transcendence with five each. Face and Humility entered the centering mean, but not these scores, because each spans neighboring dimensions. Participants completed one block per phase, with no repeated portraits and item order randomized within each block and phase. Published reliability estimates use three items per refined value and do not validate these one-item-per-value blocks [113]; we therefore pre-validated them at the analyzed higher-order level (§3.1.1). All outcomes are multi-item composites: higher-order scores average three to five items, and the personal-focus axis compares seven with ten. A sensitivity check assigning Face to Conservation and Humility to Self-Transcendence yielded a nearly identical axis ($r = .985$), larger Phase-2 contrasts, and Phase-3 contrasts still near zero.

The pre-study recruited 100 people under the study criteria. They completed all 57 items in a randomized block order, one block at a time. Block higher-order scores correlated 0.88–0.97 with full-instrument scores. All 12 block-to-full and all 12 block-to-block comparisons were equivalent within 0.5 scale points by two one-sided tests [71]. Single-block intraclass correlations were 0.66–0.84 (mean 0.76), and three-block correlations were 0.85–0.94 [119]. Mean pairwise correlation was 0.79; full-instrument Cronbach’s α was 0.86–0.93. These results support the 19-item parallel forms at the higher-order level (Table 3).

Blocks retained small mean offsets, reaching 0.37 scale points for Openness to Change and Self-Enhancement; Self-Transcendence showed no block effect ($p = .589$). We counterbalanced block order independently of condition and included block as a covariate in every model. Thus, offsets were not systematically tied to phase or condition and were adjusted in condition-by-phase contrasts (§3.1.4).

3.1.3 From ratings to priorities. Parallel forms make phases comparable, but value priorities also require separating relative importance from response-scale use: rating every item 5 or every item 3 expresses the same priorities. Schwartz

therefore recommends subtracting each person’s mean rating (MRAT) across all value items to express relative importance rather than general scale use [112]. For each phase’s parallel form, we subtracted its MRAT across all 19 responses, including Face and Humility, from its four higher-order scores [112]. We also report uncentered group means and MRAT shifts because centered scores can decrease as MRAT increases, even when raw group means change little.

Centering makes the four group scores compositional. They sum to approximately zero, so a rise in one mechanically pushes others down [2]. This dependence suits relative priorities, but reduced between-person spread in centered profiles cannot establish declining absolute endorsement. We therefore separate profile direction from magnitude for RQ2 and repeat the spread analysis with uncentered scores and MRAT (Appendix A).

We computed the primary personal-focus axis from the centered scores. Personal focus is the item-count-weighted mean of Openness to Change (OC) and Self-Enhancement (SE); social focus is the item-count-weighted mean of Conservation (CO) and Self-Transcendence (ST). The axis is their difference, positive toward personal focus:

$$\frac{4 \text{ OC} + 3 \text{ SE}}{7} - \frac{5 \text{ CO} + 5 \text{ ST}}{10}.$$

The weights keep both composites on the raw PVQ-RR scale, so zero indicates equal weight on the two poles. Face and Humility enter only through MRAT.

3.1.4 What the design estimates. Our estimand is a change rather than a score level. Let $\mu_{c,p}$ be the adjusted mean for condition c at phase p , and B be Baseline. For each conversational condition and $p \in \{2, 3\}$,

$$\tau_{c,p} = (\mu_{c,p} - \mu_{c,1}) - (\mu_{B,p} - \mu_{B,1}).$$

Thus, $\tau_{c,p}$ is the Phase-1 change relative to the non-interactive AI control.

The contrast accounts for the shared dilemma–advice–PVQ-RR sequence, with counterbalancing and covariate adjustment addressing form and order differences (§3.2.2). We report $\tau_{c,p}$ as the primary result and each condition’s change for context.

3.2 The Dilemmas

Value priorities become most visible when judgments pit conflicting values against each other, and advice-giving foregrounds abstract, desirability-based considerations (§2.2.1). Each dilemma, therefore, pitted personal against social focus, matching our primary axis. In every phase, participants read a dilemma in which someone else sought advice and wrote their advice.

3.2.1 Designing and validating the dilemmas. We used third-party advice tasks to hold the conflict constant while requiring a value-laden stance. Participants’ own dilemmas would introduce personal stakes we could not equate across the sample; shared dilemmas made task conditions comparable for examining priorities and written reasoning. The inventory immediately followed the advice. Baseline followed the same dilemma–advice–inventory path (§3.3.2), so the conversational contrast estimates the increment over an AI-generated consideration.

We selected three dilemmas from VALACT-15K, a corpus of real advice-seeking Reddit posts mapped onto Schwartz’s values [53]. Selection required comparable reading demands, the same personal-versus-social conflict across different everyday decisions, and explicit mention of considerations aligned with both poles. We first retained posts of 200–600 words; an LLM shortlisted 30 in which the four higher-order values supported distinct actions. Three researcher consensus rounds narrowed these to 12, then 6, then 3, excluding posts involving sexual content, potentially distressing

material, or physical or psychological abuse. The retained posts preserved the same value structure across career, family, and household decisions.

The retained dilemmas preserved each poster’s first-person voice. We removed identifying details, including ethnicity markers.

Job asks whether a person should accept a better-paid, more senior position in another city or remain in a preferred city with a partner who likes the current city but dislikes his job.

Family concerns an 18-year-old with a sports scholarship who wants to become a personal trainer. His stepfather wants him to study law to preserve the family’s reputation, while his mother works night shifts and wants peace at home.

Move-out concerns a 23-year-old who pays half the household rent and provides most of the care for a younger sibling with a learning disability. He has signed a tenancy agreement two hours away while the family’s finances deteriorate.

Together, the dilemmas vary in decision context while holding the personal-versus-social conflict constant. We did not score the recommendation direction; instead, the advice task required active engagement with each dilemma and provided RQ4’s behavioral record.

3.2.2 The advice task. At each phase, participants wrote advice in a plain editor with pasting and drag-and-drop disabled. Responses required at least 30 words, with no upper limit. This minimum followed evidence that Divergent Semantic Integration (DSI) scores stabilize for texts of roughly 30–50 words [60].

We counterbalanced dilemma and PVQ-RR block order with six Williams-balanced Graeco-Latin square sequences [139]. Each participant encountered every dilemma and block once; each appeared in every phase across sequences, with reversed sequences balancing first-order carryover. Item order was randomized within each block and phase. We rotated sequences within each between-participant condition. Because 50 participants cannot divide equally among six sequences, models adjusted for block, dilemma, and sequence (§3.7).

3.3 The LLM Conversation and the Non-Interactive AI Control

We designed the interaction to support participants’ deliberation. An LLM prompted to stay neutral can still move preferences after a short exchange [141], so the thinking-partner stance controls the manipulation. One prompt, identical across **ChatGPT**, **Claude**, and **Gemini**, instructed models to support reasoning while leaving recommendations to participants, with no target recommendation to promote.

Within these role constraints, the conversation was unscripted after a shared opener and without a response template [146]. Content and emphasis could therefore develop organically with the participant’s contributions in each exchange, so that similarity across exchanges and subsequent advice could be examined empirically.

3.3.1 LLM conversation. The shared prompt prohibited advocating for values, recommending actions, or settling the dilemma. The system prompt varied only in the dilemma text; replies remained unscripted. The role clause reads:

You are a thinking partner helping the reader reason through what to recommend, never telling them what to recommend and never settling it for them.

To avoid eliciting agreement with an initial participant lean [20, 56, 117], every conversation began with the same uneditable click-to-send message:

I just read this situation and I have to write up what I'd recommend. Before I do, what are the main things worth weighing here?

Participants then typed freely with the dilemma visible. The interface identified the model only as an AI assistant, subtitled “Thinking partner”. The continue button appeared after five participant messages, or when the ten-minute cap elapsed.

Fig. 3. **Study interface in a conversational condition.** The scrollable dilemma remains above the exchange. A shared “AI assistant” header and a “Thinking partner” subtitle conceal the provider’s identity. *For Baseline, the text input was disabled.*

Generation settings were identical across the three models. Calls went through OpenRouter to openai/gpt-5.4, anthropic/claude-sonnet-4.6, and google/gemini-3-flash-preview, with temperature 0.7. The request set no token cap, top_p, or seed. Median first replies ranged from 87 to 191 words across providers (\$4.1).

3.3.2 The non-interactive AI control. Baseline retained exposure to AI-written text, AI attribution, and the interface, but offered no exchange (§2.2.2 and §2.2.1). For each dilemma, the same three models restated the facts and considerations already expressed in the dilemmas. This changed their presentation without adding new considerations or advocacy.

An LLM synthesized overlapping content into one fixed response per dilemma. Pairwise cosine similarities among the source responses were 0.836 for **Job**, 0.724 for **Family**, and 0.763 for **Move-out**. Each synthesis spanned 345–359 words and had cosine similarity above 0.85 to every source. The control was thus synthesized across providers rather than provider-matched.

Participants read the response under the same AI-assistant header and “Thinking partner” subtitle, retaining the dilemma panel and message format but removing the composer. Everyone assigned a dilemma read the same response,

then completed the same advice, PVQ-RR, and perception tasks as conversational participants. Thus, the contrast compared live, non-directive exchange with fixed presentation of existing considerations. Time on task outside the manipulation window did not differ across conditions (§4.1). The fixed passage also served as a known source for validating the text-overlap measures (§4.5.1).

3.4 Advice, Perception, and Intake Measures

The PVQ-RR is the primary outcome measure. Advice texts address RQ4, perception measures address RQ3, and intake measures describe the sample.

3.4.1 Advice texts. We measured traces of the AI source, semantic focus, and similarity of the written advice across participants. Let a_i be participant i 's Phase-2 advice and s_i the concatenated messages they received. Bold symbols denote ℓ_2 -normalized embeddings; $\text{unit}(\mathbf{v})$ normalizes a vector.

Each advice text was compared with its own source and a yoked source from the same provider and dilemma. Within each cell, participants were paired in data order with the next participant, wrapping around so each source served once as a yoke. For Baseline, we compared the passage read with one for an unseen dilemma as a positive control; identical fixed passages would yield no contrast.

We measured resemblance lexically and semantically. Lexical overlap was

$$m_n(a, s) = \frac{|G_n(a) \cap G_n(s)|}{|G_n(a)|},$$

where $G_n(t)$ is the set of distinct content-word n -grams after lowercasing and removing a fixed English stopword list. We scored $n = 1, 2$, and 3 and report the two-word score as phrase overlap. Semantic overlap was $m_{\cos}(a, s) = \mathbf{a}^\top \mathbf{s}$.

To distinguish uptake specific to an exchange from content shared across its provider and dilemma, we projected each source embedding onto a centroid of other sources and retained the orthogonal remainder:

$$\mathbf{c}_i = \text{unit}\left(\frac{1}{k} \sum_{j \in K_i} \mathbf{s}_j\right), \quad \mathbf{u}_i = \text{unit}(\mathbf{s}_i - (\mathbf{s}_i^\top \mathbf{c}_i) \mathbf{c}_i),$$

Here, K_i is a fixed random set of k other participants in the same cell, $\mathbf{c}_i$ its centroid, and $\mathbf{u}_i$ the normalized residual. For comparable centroid precision, k was one less than the smallest provider cell for each dilemma.

We measured semantic focus with Divergent Semantic Integration (DSI), adapted to sentence pairs [60]:

$$\text{DSI}(a) = \frac{2}{S(S-1)} \sum_{p < q} (1 - \mathbf{x}_p^\top \mathbf{x}_q),$$

where $\mathbf{x}_1, \dots, \mathbf{x}_S$ are the embeddings of the text's S sentences. High DSI indicates more distinct ideas; low DSI indicates greater semantic focus. We split on sentence-final punctuation, used semicolons and line breaks when fewer than two segments remained, and retained segments of at least three words.

Between-person similarity was each text's cosine distance from the other texts in the same condition, phase, and dilemma:

$$d_i = 1 - \mathbf{a}_i^\top \text{unit}\left(\frac{1}{n_c - 1} \sum_{j \neq i} \mathbf{a}_j\right),$$

where n_c is the cell size. Lower d_i indicates greater between-person similarity [4]. The measure is undefined for cells with fewer than three texts.

All semantic measures used `text-embedding-3-small`. We also recorded advice length and sentence count. Vocabulary range used the moving-average type-token ratio over a 25-token window [25, 83], and repetition used a compression-based score residualized for length.

3.4.2 Perception measures. After Phase-2, participants rated their LLM on seven measures covering interaction, ability, and humanness [138]. Single 1–7 items adapted from Cheng et al. [20] measured response quality, whether LLMs behavior in this situation was right or wrong, and willingness to reuse it for similar questions. Godspeed likeability and perceived intelligence scales [11] each averaged five 1–5 semantic differential pairs. Performance and moral trust used the Multi-Dimensional Measure of Trust [127], each rated 0–7. Table 5 reports Cronbach’s α for every multi-item measure.

All 200 participants completed these measures, including Baseline, in which participants rated the AI assistant’s response they had read. RQ3 asks whether the three providers differed and whether ratings tracked the Phase-2 shift, so analyses use the 150 conversational participants; Baseline’s ratings are reported descriptively alongside them (§4.4).

3.4.3 Intake. The intake questionnaire describes the sample. It recorded age group, gender, race and ethnicity, education, whether English was the participant’s primary language, and AI-tool familiarity and use frequency (each on a 1–5 scale). Participants also completed the Short Schwartz Value Survey (SSVS) once, rating ten values from 0 to 8 [78].

3.5 Procedure

Participants joined through Prolific and completed a fixed-order session in a custom application (Figure 4). We measured priorities before manipulation, immediately after, and after a further task, each with a different dilemma assigned by the square in §3.2.2.

Intake. After reading study information and consenting, participants completed demographics and the Short Schwartz Value Survey. They were told the study concerned advice-giving and LLM assessment, without disclosure that it measured value-priority change.

Phase-1. Participants read their first dilemma, wrote at least 30 words of advice, and completed a PVQ-RR block. No condition involved AI, establishing the untreated starting level for both later phases.

Phase-2. Participants read a second dilemma. Conversational participants talked with their assigned model while the dilemma remained visible, proceeding after five messages or the time cap. Baseline scrolled through and read the assistant’s fixed response on the same screen. All then wrote advice, completed a PVQ-RR block, and rated the AI just encountered.

Phase-3. To test carryover and outcome-specific durability (§2.2), participants read the remaining dilemma, wrote advice without AI in any condition, and completed the final PVQ-RR block, measuring what remains after the LLM is gone.

Debriefing. We disclosed the value-priority-shift objective and named the three commercial systems as examples without identifying participants’ assigned model. Participants could withdraw their data, then return to Prolific with a completion code.

3.6 Participants

We recruited 200 U.S.-based adults (50 per condition) via Prolific who were fluent in English. We ran an a priori power analysis for a four-condition between-participant comparison at $\alpha = .05$. Fifty participants per condition give 85% power to detect a medium effect (Cohen’s $f = .25$) and more than 99% power to detect a one-standard-deviation difference

Fig. 4. **Study procedure. Conditions differ only at Phase-2, step 2.** The three conversational arms talk with a live model for at least five messages under a ten-minute cap; Baseline reads a fixed response to the same dilemma, synthesized from outputs of the same three models, from the same AI assistant on the same screen with the composer removed. Dilemma order and PVQ-RR block order are Williams-balanced.

between any two conditions [90]. Estimates of spread carry wider intervals than estimates of means at the same sample size, so a design that can resolve a mean shift (RQ1) can still miss a change in spread (RQ2). We therefore report a minimum detectable effect at 80% power beside every null.

The sample included 99 women, 99 men, and 2 nonbinary participants; 57 were aged 18–29, 98 aged 30–49, 37 aged 50–64, and 8 aged 65 or older. Intake data, including SSVS scores, did not differ significantly across conditions (all $p \geq .08$; SSVS mean rating, Kruskal–Wallis $H(3) = 3.15$, $p = .370$).

Participants received \$11.96/hr; median session time was 28.8 minutes ($IQR = 22.0$ – 35.3). All 200 participants completed all three PVQ-RR blocks and entered the analysis.

3.7 Data Analysis

We fit random-intercept mixed models by restricted maximum likelihood in statsmodels [115], used scipy for tests, correlations, and ANOVAs, and set seed 20260805 for bootstrap, permutation, and yoking streams. We checked model convergence and fixed-effects rank. Unless noted otherwise, each outcome used

$$\text{score} \sim \text{phase} \times \text{condition} + \text{pvq_block} + \text{dilemma} + \text{sequence} + (1 \mid \text{person}),$$

with Baseline as the reference. A single fit supplied all phase changes and condition-minus-Baseline contrasts, holding block, dilemma, and sequence fixed. Within-participant contrasts had 388 degrees of freedom: 600 observations minus 200 participants minus the within-person fixed-effects rank of 12.

Effect sizes, multiplicity, and nulls. We report 95% confidence intervals and Glass's $d_G = \widehat{\Delta}/s_1$ [39], using the pooled Phase-1 standard deviation across conditions as a fixed, untreated scale; paired own-versus-yoked comparisons use d_z . All tests are two-sided at $\alpha = .05$, with realized-standard-error MDEs at 80% power for null results.

Holm adjustment [50] covered these families: three condition-minus-Baseline contrasts per phase for the axis, spread, DSI, and advice distance; four higher-order groups per condition and contrast; three provider pairs per phase; perception measures, with pairwise tests only after a significant omnibus; and three n -gram lengths per condition. Own changes and Phase-2-to-Phase-3 decay contrasts are descriptive and unadjusted.

RQ1: value-priority shift. RQ1 mixed models tested priority shifts in the personal-focus axis and four centered higher-order scores, contrasting each condition with Baseline in Phases 2 and 3 and comparing Phase-2 with Phase-3 for decay.

Because values form a circle, we also rewrite each condition's mean change Δ across the four groups as an exact change of basis, not a fitted model. Openness to Change, Self-Transcendence, Conservation, and Self-Enhancement sit at 0° , 90° , 180° , and 270° ,

$$\Delta(\theta) = a_0 + a \cos \theta + b \sin \theta + q \cos 2\theta.$$

Amplitude is $\sqrt{a^2 + b^2}$ and angle is $\text{atan2}(b, a)$, with personal focus at 315° . The q term is the quadrupole, the part of the change that no coordinated turn can produce. Intervals are derived from 10,000 bootstrap resamples of participants within each condition, with bearings averaged as unit vectors so that intervals do not wrap at 0° . We compared the largest gap between the three providers' bearings with the distribution of that gap under permuted provider labels, which asks whether the observed agreement is what three providers pushing in one direction would produce. We also re-estimated the Phase-2 contrast while adjusting for each participant's Phase-1 score and tested whether Phase-1 means differed across conditions.

RQ2: similarity of profiles. At each phase, to test for homogenization, we scored the leave-one-out distance from each participant's four-value profile $\mathbf{x}_i$ to their condition's mean with that person omitted,

$$d_i = \|\mathbf{x}_i - \bar{\mathbf{x}}_{(-i)}\|.$$

We entered these distances into the same mixed model, adapting the leave-one-out diversity statistic used for AI-assisted texts to value profiles [4, 32].

To distinguish directional convergence from changes in the spread of profile magnitudes, we repeated the spread calculation separately for profile direction (unit vectors) and magnitude (Euclidean length). For this decomposition, we excluded 12 participants with zero-magnitude profiles in at least one phase, for which direction is undefined, and used the remaining 188 for all components. To account for dependence through shared centroids, permutation tests reshuffled condition labels and rebuilt all centroids [5, 6]. Appendix A reports six spread definitions, leave-one-participant-out estimate ranges, and checks adjusting for Phase-1 spread or individual MRAT change.

RQ3: perceptions. RQ3 analyzed provider differences and associations with the Phase-2 shift in the 150 conversational participants. We compared providers on seven measures using one-way analyses of variance, Holm-adjusted p-values,

and Welch pairwise tests after significant omnibus tests. We report Baseline ratings descriptively in a four-condition comparison. Because the measures intercorrelate, we also tested a favorability composite averaging their z-scores. We regressed the signed Phase-2 axis shift on the seven measures and computed partial correlations after residualizing both sides on provider. We did not use distance between a participant’s Phase-1 and Phase-3 value vectors as shift magnitude: these vectors use different parallel forms, so a norm would rectify form error rather than average it out.

RQ4: traces in the advice texts. For Phase-2 advice, written immediately after the AI exposure, uptake was the own-minus-yoked overlap (§3.4.1),

$$\Delta_i = m(a_i, s_i) - m(a_i, s_{y(i)}),$$

where m is either overlap measure and $y(i)$ the yoked participant. Matching sources on provider and dilemma isolates resemblance specific to the participant’s exchange. One-sample t tests compared Δ_i with zero; follow-up semantic tests replaced s_i with u_i to assess uptake beyond shared source content. The RQ1 mixed model also tested DSI, sentence count, vocabulary range, length-residualized repetition, and leave-one-out advice-embedding distance. Permutation tests assessed whether dilemma or condition structured the first two embedding principal components; inference applies to that two-dimensional map, not the full embedding space.

Manipulation checks. We compared conversational conditions on advice length, total words typed excluding the scripted opener, and words per typed turn. Because counts are right-skewed, we tested log words with Welch tests and Holm adjustment across three provider pairs. We compared LLM verbosity likewise, including first-reply length after the identical opener. To account for provider verbosity differences, we added words received as a covariate on the Phase-2 axis and tested provider differences with and without it. Within-provider uniformity was mean pairwise cosine across different participants’ assistant turns within each dilemma, compared with the corresponding quantity across participants’ own messages.

4 Results

The primary value-shift and whole-profile spread analyses included all 200 participants who completed the three PVQ-RR blocks (50 per condition). We implemented the Williams-balanced design for counterbalancing [136]. At each phase, the four conditions had identical scenario sequences and PVQ-RR block compositions. Internal consistency was high for most perception measures (Table 5).

In this section, we present the results of our four research questions. We first establish that participants engaged similarly with the three LLMs, and that their visible differences do not confound the effects. We then present RQ1, which examines how value priorities changed before and after the LLM conversations. After that, in RQ2, we examine whether participants’ value profiles became less dispersed in direction or magnitude after the LLM conversation. Then, in RQ3, we present whether participants’ perception measures of the three LLMs are related to their value shifts. Finally, we move to RQ4, presenting whether the LLMs left their traces in the participants’ written advice. In each research question, we present our statistical tests and robustness analyses.

Unless noted otherwise, all estimates come from the mixed models in §3.7. We use Baseline as the reference condition and apply Holm correction within each family of tests. For null results, we report the minimum detectable effect (MDE) at 80% power. We do not treat a nonsignificant result as evidence of no effect. Appendix A reports the supporting analyses. Detailed results are included in the supplementary materials.

4.1 Manipulation check

Participants engaged with all three LLMs at similar levels. Advice length, total words typed, and words per turn were comparable across conditions (smallest Holm $p = .585$; minimum detectable ratio $\approx 1.4\times$), and each condition had a median of five turns. Each LLM also gave similar replies across participants. Replies from the same LLM had mean pairwise cosine similarities of 0.882–0.895, compared with 0.492–0.562 among participants' messages.

The LLMs differed in first-reply length (medians: 191 words for **Claude**, 151 for **ChatGPT**, and 87 for **Gemini**; $F(2, 147) = 267.47$, $p < .001$). Words received did not predict the Phase-2 shift (-0.030 per 100 words; minimum detectable slope 0.098). Adjusting for words received did not change the comparison among the three providers (Table 6).

Time on task differed only at Phase-2. Phase-1 durations of 8.1–9.6 minutes and Phase-3 durations of 5.9–6.5 minutes were comparable across conditions ($H(3) = 1.37$, $p = .714$; $H(3) = 1.63$, $p = .652$). At Phase-2, the conversational conditions took 12.4–13.7 minutes compared with 9.1 minutes for Baseline, a median gap of 3.7 minutes ($H(3) = 20.11$, $p < .001$). Because the conversation required at least five messages, the design does not separate interaction from the additional time it required.

4.2 RQ1: LLM conversations temporarily shifted value priorities toward personal focus

In our study, each dilemma pitted personal interests against social interests. To highlight the value shift, we therefore used the personal focus score on the Personal Focus versus Social Focus axis as the primary outcome. The score equals Openness to Change and Self-Enhancement minus Conservation and Self-Transcendence, weighted to remain on the raw PVQ scale. All four conditions began on the social side of the Personal Focus versus Social Focus axis (Phase-1 means -0.29 to -0.47). At Phase-2, the three LLM conditions moved to the personal side. They moved back by Phase-3. Baseline instead rose gradually across all three phases (Figure 5).

Fig. 5. **Reported value priorities moved toward personal focus following the exchange and moved back by the next task.** Mean personal-focus score at each phase, in raw PVQ scale points, with 95% confidence intervals; $n = 50$ per condition. Each score is measured after that phase's dilemma and advice task. The three LLM conditions rise sharply at Phase-2 and fall by Phase-3. Baseline rises gradually. Zero indicates equal weight on personal and social focus.

From Phase-1 to Phase-2, personal focus increased relative to Baseline by $+0.429$ in **ChatGPT** (Glass $d = 0.51$, Holm $p = .004$), $+0.384$ in **Claude** ($d = 0.46$, $p = .008$), and $+0.312$ in **Gemini** ($d = 0.37$, $p = .020$). The shifts were similar across providers: the largest gap was 0.145 scale points, compared with an MDE of 0.372 (Figure 6).

Fig. 6. **The Phase-2 value shift did not persist to Phase-3.** Change in the personal-focus axis from Phase-1, with 95% confidence intervals. Filled dots show Phase-2, and hollow rings show Phase-3. The upper rows show each LLM condition's change; the lower rows show its contrast with Baseline. The secondary axis expresses the same estimates as Glass d , using the Phase-1 SD (0.837). Color marks indicate estimates that survive Holm correction.

By Phase-3, the LLM contrasts with Baseline ranged from -0.062 to $+0.083$, and none survived correction. From Phase-2 to Phase-3, scores fell by 0.198 – 0.265 across the LLM conditions (all $p \leq .036$), returning toward their Phase-1 levels. Baseline changed by only $+0.108$.

Self-Enhancement accounted for the shift, increasing by $+0.537$ to $+0.586$ relative to Baseline (all Holm $p \leq .002$). No condition-by-value contrast remained significant at Phase-3. Centered Self-Transcendence also fell, but the raw score changed little ($\Delta = -0.01$ to -0.20) while participants' mean rating across all PVQ-RR items rose ($\Delta \text{MRAT} = +0.07$ to $+0.26$). Subtracting this overall rise made centered Self-Transcendence appear lower; participants did not report a comparable decline in concern for others.

Using Schwartz's value circle [114], we summarized the direction and magnitude of each condition's mean change (Table 1). At Phase-2, rotation accounted for at least 99% of the change in each LLM condition. The rotations were within 15 – 25° of the personal-focus pole, and the personal-focus axis accounted for 90 – 97% of their amplitude. The three providers' bearings spanned only 10.4° , a gap that small or smaller arising in 22% of permutations of the provider labels, so their directions are consistent with one common bearing; the per-condition intervals span roughly $\pm 20^\circ$. Baseline moved in a different direction with about one-third the amplitude. By Phase-3, the LLM amplitudes had fallen to 0.22 – 0.24 , indicating a weaker rotation in the same general direction (Figure 7).

The Phase-2 shift was unchanged after adjustment for Phase-1 scores (Table 6).

4.2.1 The shift is not a property of the measurement setting. Every PVQ-RR block followed a dilemma and an advice task, so the measurement setting itself could in principle produce a shift (§3.1.4). The comparisons across conditions and phases do not support that account.

Baseline followed the same dilemma–advice–PVQ-RR sequence and met the same AI assistant, but read rather than conversed (§3.3.2). Its Phase-1-to-Phase-2 movement had an amplitude of 0.150 [$0.050, 0.278$] and a bearing of 17° ,

Fig. 7. **The value shift was a temporary rotation toward personal focus.** Mean value profiles across the four Schwartz higher-order poles: Self-Transcendence (ST), Self-Enhancement (SE), Openness to Change (O), and Conservation (C). Radius is each value's deviation from the participant's mean rating across all 19 items; rings mark -0.5 , 0 , and $+0.5$. Dashed, solid, and dotted outlines show Phases 1, 2, and 3. The conversational conditions shift toward the personal-focus axis in Phase-2 and return by Phase-3, whereas Baseline drifts without returning.

Table 1. The Phase-2 change in value priorities forms one rotation. Amplitude gives the size of each condition's mean change on the value circle, and angle gives its direction. Rotation share is the percentage explained by the two rotation components. The remaining percentage is the quadrupole component, which does not describe a rotation. 0° is Openness to Change, and 315° is the personal-focus pole. Brackets give 95% confidence intervals.

Condition	Amplitude	Angle	Rotation share
<i>Phase-1 $\rightarrow$ Phase-2</i>			
Baseline	0.150 [0.050, 0.278]	17° [325° , 67°]	74.7%
ChatGPT	0.412 [0.222, 0.621]	300° [280° , 326°]	99.8%
Claude	0.394 [0.281, 0.522]	298° [280° , 316°]	99.1%
Gemini	0.363 [0.213, 0.539]	290° [269° , 311°]	99.5%
<i>Phase-1 $\rightarrow$ Phase-3</i>			
Baseline	0.168 [0.071, 0.293]	345° [300° , 28°]	54.1%
ChatGPT	0.240 [0.107, 0.409]	299° [269° , 346°]	99.8%
Claude	0.228 [0.133, 0.348]	313° [279° , 345°]	98.5%
Gemini	0.221 [0.094, 0.392]	265° [224° , 311°]	99.7%

about one-third the amplitude of the conversational conditions and in a different direction from their 290 – 300° bearings (Table 1). The adjusted conversational contrasts remained $+0.312$ to $+0.429$. Phase-3 repeated the same measurement sequence without an LLM, but its contrasts with Baseline ranged from -0.062 to $+0.083$ and none survived correction. The conversational conditions also fell 0.198 – 0.265 from Phase-2 (all $p \leq .036$). The shift therefore appeared at the manipulation phase rather than whenever the questionnaire followed a value-laden task.

The pattern was also not tied to one dilemma or a few salient value items. Rotation accounted for at least 99% of the Phase-2 movement in every conversational condition. Dilemma order was counterbalanced, and the models held dilemma fixed.

Still, participants can move in the same direction without becoming more alike. RQ2 tests whether they became more similar to one another.

Summary. LLM conversations temporarily moved value priorities toward personal focus by 0.31–0.43 scale points over Baseline ($d = 0.37$ – 0.51). Higher Self-Enhancement scores accounted for this shift. We observed the same directional pattern along the personal-versus-social axis across all three LLMs.

4.3 RQ2: Value profiles became less varied in magnitude after conversation, not more similar

Participants can shift in the same direction without becoming more alike. We therefore measured the distance between each participant’s value profile and the average profile for their condition to test whether they became more alike after LLM conversation. We left that participant out when calculating the condition average. Using the same mixed-model structure as RQ1, we compared changes in these distances between each LLM condition and Baseline.

At Phase-2, the spread contrasts with Baseline ranged from -0.068 to -0.275 , and none survived correction (smallest Holm $p = .061$). The difference appeared at Phase-3, when spread fell by 7.6%–22.4% in the LLM conditions but rose by 11.5% in Baseline. Relative to Baseline, the Phase-3 contrasts were -0.353 for ChatGPT (Holm $p = .006$), -0.436 for Gemini ($p < .001$), and -0.222 for Claude ($p = .061$). The three LLM providers did not differ at either phase.

The change in spread, therefore, occurred later than the value shift: for the pooled conversational conditions, the Phase-3 contrast was 0.190 more negative than the Phase-2 contrast ($p = .049$). Both sides contributed. Spread in Baseline rose by $+0.145$, whereas the spread in the LLM conditions fell by a median of 0.150, with decreases in all three conditions (Figure 8).

Fig. 8. **Between-person spread contracted only at the later endpoint.** Each dot shows one participant’s change in distance from the average profile for their condition. Values to the left show less spread; values to the right show more spread. Each outline shows the distribution of the 50 values in that row, using the same bandwidth and height scale across rows. The first two panels show changes from Phase-1 to Phases 2 and 3. Diamonds show condition means with 95% bootstrap intervals. The right-most panel compares each LLM with Baseline and shows the MDE band (± 0.330). Color marks the significance.

Pooling the conversational conditions, we separated directional spread from spread in profile magnitude (Table 2). The *contraction* in spread at Phase 3 reflected a reduction in between-person variation in profile magnitude. The Phase-3

difference in changes relative to Baseline was -0.255 ($p = .004$), equivalent to 39% of Phase-1 spread. We detected no corresponding contraction in directional spread (-0.038 , $p = .601$). A circular decomposition showed the same pattern. Angular spread changed by only -5.2° (MDE 22.8°), while amplitude spread decreased descriptively by -0.111 .

The Phase-3 contraction was robust to randomization inference, alternative definitions of spread, adjustment for Phase-1 spread, and leave-one-participant-out analyses (Table 4). We found no evidence that participants converged on a common value ranking. The contraction instead reflected reduced between-person variation in profile magnitude. §4.5.3 tests whether their written advice became more alike.

Table 2. Changes in spread of whole profiles, directions, and magnitudes, comparing pooled participants from [ChatGPT](#), [Claude](#), and [Gemini](#) with Baseline ($N = 188$). Spread is calculated within each original condition. Estimates are differences in changes from Phase-1 to each later phase; negative estimates indicate greater contraction in the conversational conditions. Percentages express Phase-3 contrasts relative to Phase-1 spread.

Space	P1 $\rightarrow$ P2		P1 $\rightarrow$ P3		P3 as % of
	Estimate	p	Estimate	p	P1 spread
Whole profile	-0.127	.267	-0.346	< .001	-26.7%
Shape only	$+0.143$	.037	-0.038	.601	-4.8%
Magnitude only	-0.075	.446	-0.255	.004	-39.0%

Summary. By Phase-3, value profiles were less spread out relative to Baseline. The pooled decomposition located this contraction in the spread of profile magnitudes, with no detected contraction in directional spread.

4.4 RQ3: All three LLMs were rated favorably, and we detected no provider differences

Differences in how participants viewed the LLMs could explain the value shift. For example, a better-liked LLM might have been more influential. We therefore tested whether the three LLMs differed on the perception measures and whether those measures were associated with participants' value shifts. The tests below are estimated on the 150 participants in the LLM conditions; we report Baseline ratings descriptively at the end of this section.

Every LLM received a mean rating above the midpoint of every scale, with means ranging from 56% to 80% of the scale range. No measure differed by provider after Holm correction; the largest observed gap was 0.70 scale points, compared with an MDE of 0.73 (Figure 9; Table 5).

The seven perception measures were strongly correlated (mean $r = 0.78$), so we summarized them with a standardized composite favorability score ($\alpha = 0.96$). This score also did not differ by provider, $F(2, 147) = 1.30$, $p = .275$.

The seven perception measures jointly explained 7.5% of variation in the Phase-2 shift, but the regression was not statistically significant ($p = .131$). No individual Pearson correlation survived Holm correction. In the separate partial-correlation analysis, adjusting for provider left the strongest association, with response quality, essentially unchanged. These ratings do not explain the shared shift, although our sample cannot rule out modest differences between providers.

In the Baseline condition, participants also evaluated the AI favorably, with every mean above the corresponding scale midpoint. Its overall favorability score was 0.20 SD below the pooled conversational conditions, a difference we did not detect as significant ($p = .197$; MDE $d = 0.48$). We therefore detected no perceptual advantage for interaction over the fixed-response AI-attributed Baseline.

Fig. 9. **Participants rated all three LLMs favorably.** Means and 95% confidence intervals are shown as percentages of each measure’s scale range so that the 0–7, 1–5, and 1–7 scales can be compared. No measure differed by provider after Holm correction. The largest gap was 0.70 scale points for rightness, compared with an MDE of 0.73. The combined favorability score also did not differ, $F(2, 147) = 1.30$, $p = .275$.

Summary. Participants rated all three LLMs above the midpoint of every scale, and no difference between providers survived correction. These ratings also did not predict participants’ value shifts, so they do not explain the shared shift.

4.5 RQ4: Participants used language from their own LLM in their advice and wrote more semantically focused advice

We next turn from what participants reported to what they produced. At Phase-2, participants wrote about the dilemma they had just discussed with an LLM. Phase-1 occurred before the conversation, and Phase-3 used a new dilemma without an LLM. We first test whether participants reused words or ideas from their own LLM’s replies. We then test how their advice changed and whether participants assigned to the same provider wrote more similar advice.

4.5.1 Participants reused their own LLM’s words and meaning. Two texts about the same dilemma will share some words even if neither influenced the other. We therefore compared each advice text with two sets of LLM messages. The first contained the messages that the participant’s own LLM sent them. The second contained LLM messages from another participant’s conversation with the same model about the same dilemma, which we call the matched (*yoked*) conversation. This comparison holds the dilemma and LLM provider constant while varying whether the messages came from the participant’s own interaction or a matched one. Any remaining difference, therefore, captures how much more the advice resembled the messages the participant’s own LLM sent.

Phase-2 advice shared more content words with the participant’s own LLM than with the matched messages. The differences were +0.065 for ChatGPT, +0.068 for Claude, and +0.052 for Gemini ($d_z = 0.49, 0.50$, and 0.41). Semantic similarity was also higher by +0.031, +0.030, and +0.023 ($d_z = 0.91, 0.57$, and 0.56 ; all Holm $p < .001$). Two-word phrase

overlap survived correction only for **ChatGPT** (+0.026, $p = .003$; Figure 10). The longest shared sequence averaged only 1.4–1.6 content words, indicating reuse rather than verbatim copying.

As a positive control, Baseline advice more closely resembled the passage participants read than a passage about an unseen dilemma (+0.134, $d_z = 1.23$, $p < .001$).

Fig. 10. **Participants’ advice resembled their own LLM’s messages.** Panels show content-word overlap, two-word phrase overlap, and cosine similarity between the advice and source-message embeddings. Ticks show similarity to LLM messages from another participant’s conversation with the same model about the same dilemma. Dots show similarity to the messages the participant’s own LLM sent. All three providers showed differences in content-word overlap and semantic similarity.

4.5.2 Participants’ own writing became more semantically focused. We next tested whether the advice became more focused. We used Divergent Semantic Integration (DSI), the mean pairwise cosine distance among the sentences in each advice text. A high DSI means that the text covers more distinct ideas. A low DSI means that it stays focused on a narrower set of ideas. We compared each participant’s DSI across phases while holding the dilemma fixed.

Relative to Baseline, the adjusted Phase-2 DSI contrast was -0.064 for **ChatGPT** (Holm $p = .004$), -0.043 for **Gemini** ($p = .057$), and -0.029 for **Claude** ($p = .137$). All three estimates favored greater semantic focus, but only the **ChatGPT** contrast survived correction (Figure 11).

We found no corresponding changes in vocabulary, repetition, sentence count, or advice length.

The change in DSI was also temporary. By Phase-3, each LLM condition was within 0.003 of its Phase-1 level, and none differed from Baseline (MDE 0.055). Thus, semantic focus followed the same Phase-2-to-Phase-3 pattern as the value shift.

4.5.3 The influence was tailored to each conversation, and the advice did not converge. Participants can draw from their own conversations without becoming more alike as a group. To separate individualized influence from global influence, we split each participant’s LLM messages into components shared with other participants in the same condition and dilemma, and the remainder specific to that participant. We then repeated the comparison between each participant’s own conversation and another participant’s conversation with the same model about the same dilemma (§4.5.1). Advice was more similar to the participant-specific part of their own LLM’s messages than to that of the matched messages. The differences were +0.099, +0.095, and +0.066 for **ChatGPT**, **Claude**, and **Gemini** ($d_z = 0.92$, 0.60, and 0.56).

The dilemma itself strongly shaped the advice. Among all 200 Phase-2 texts, the dilemma explained 81% of variation in the two-dimensional embedding map ($p < .001$), while condition explained 0.6% ($p = .890$). The four conditions were

Fig. 11. **Advice shifted toward greater semantic focus, most clearly in ChatGPT.** Within-text diversity is the mean pairwise cosine distance among an advice text's sentences. **(A)** Cumulative distributions of each participant's Phase-1-to-Phase-2 change. **(B)** Adjusted contrasts with Baseline, shown against the MDE band (0.055). All estimates are negative; only ChatGPT survives Holm correction (-0.064 , $p = .004$).

mixed within the three dilemma groups (Figure 12). Pairwise comparisons and comparisons across phases showed the same pattern, so all convergence tests controlled for dilemma.

We detected no condition-level convergence in advice. Relative to Baseline, changes in leave-one-out cosine distance ranged from -0.0009 to $+0.0167$ (all Holm $p = 1.00$). The providers also produced similarly dispersed advice. At the participant level, uptake was not related to convergence in advice or value profiles. The exchange, therefore, left detectable traces in individual advice texts without detectable convergence across participants.

Summary. Participants aligned locally with their own LLM conversation rather than globally with one another. They reused their model's words and meaning in advice they wrote themselves. This influence was personalized through LLM replies shaped by their own questions. Their advice also shifted toward greater semantic focus as a trend without becoming shorter, more repetitive, or less lexically diverse, and returned to its Phase-1 level on the same timeline as the value shift.

5 Discussion

Our results reveal two important patterns. First, brief interactions with each of three commercial LLMs produced the same temporary reorientation of participants' reported values toward a more personal focus, with higher relative priorities assigned for Openness to Change and Self-Enhancement, over Conservation and Self-Transcendence. Higher Self-Enhancement accounted for most of this shift, while raw Self-Transcendence changed little. The movement formed

Fig. 12. **Advice grouped by dilemma, not by provider** All 200 Phase-2 advice texts in a single embedding landscape. Height is the density of the pooled sample, and color is the condition, interleaved throughout. Three islands appear, one per scenario: 81% of the variance in this map is scenario ($p = .0001$) and 0.6% is condition ($p = .89$).

a coherent rotation around Schwartz’s value circle, appeared only during the LLM phase, and had receded by the next task.

Second, this reorientation occurred without detectable convergence in value directions or advice. Their advice retained words and meaning from their own exchanges and became more semantically focused. The later contraction in value-profile spread in Phase-3 instead reflected reduced between-person variation in profile magnitude. Participants also rated all three LLMs favorably, but these perceptions neither distinguished the providers nor explained the shift.

We begin by interpreting the effects on participants’ value priorities as a temporary reorientation that occurs during the period in which judgment was being formed. We then turn to its direction. Personal focus is culturally situated and corresponds to the broader WEIRD-aligned orientation documented in prior audits of commercial LLMs. We consider what it means that three systems moved participants along this shared axis through locally different exchanges, and how the common movement can occur without detectable convergence in value directions or advice. Together, these findings raise implications for how HCI understands LLMs’ impacts on the homogenization of outputs users produce and on their values, and evaluates the neutrality of non-directive LLM decision support.

5.1 A Temporary Reorientation of Value Priorities

A conversation lasting no more than ten minutes shifted participants’ reported value priorities toward personal focus by 0.31–0.43 scale points over the non-interactive AI control ($d = 0.37$ – 0.51). The pattern appeared independently

in the ChatGPT, Claude, and Gemini conditions, under the same thinking-partner prompt and opening question. By Phase-3, the contrasts with Baseline had shrunk to between -0.062 and $+0.083$, and none survived correction. The mean profiles in all three LLM conditions, therefore, moved around Schwartz’s value circle in the same direction and had returned toward their earlier positions by the next task.

Value theory provides a direct way to interpret this timing. A person’s broader value hierarchy generally changes slowly, through sustained experience and identification [9, 10, 63]. The values that become active during a particular judgment are more responsive to context, and these activated values are especially predictive of the choice made at that moment [106, 133]. Research on construct accessibility similarly shows that recently activated ideas can organize subsequent judgment before their influence weakens with time [47, 49, 121]. The Phase-2 movement fits this shorter process: the conversation temporarily changed the relative prominence of the values as participants reasoned and responded.

The timing of this effect is practically significant, as values active during a judgment are especially likely to organize that judgment [106, 133], and decision-support interactions often occur while users are forming a recommendation or deciding what to do [19]. A shift concentrated in this interval can therefore shape reasoning even when it recedes before a later task. This implication also matters for systems that elicit values through an LLM. A profile collected immediately after an exchange may partly reflect priorities made salient by the elicitation setting itself. Pre-interaction measurement, independent elicitation, or delayed reassessment would help distinguish a user’s broader priorities from those made prominent during the exchange.

One way to picture the result is as a compass briefly deflected by a nearby magnetic field: its reading turns under a local influence and relaxes once that influence passes. The analogy captures both the geometry and timing of the result. Rotation accounted for at least 99% of the Phase-2 movement in every LLM condition, meaning that the four higher-order values turned together around Schwartz’s circle. Baseline participants completed the same measurement sequence and encountered the same AI framing, yet showed a smaller, gradual movement on a different bearing. This image connects to Riedl et al. [99], who describe interaction with LLMs as a “social forcefield” whose effects extend into subsequent interactions with other people. The field observed here followed a shorter trajectory: its strongest effect was concentrated around the LLM interaction and had weakened by the next task.

This shorter trajectory adds a different timescale to the growing literature on carryover from human–AI interaction. Previous work has found that LLM-assisted writing can shift subsequent attitudes [57, 140], that users’ confidence can remain aligned with an AI advisor in later unaided decisions [76], and that conversational effects can extend to self-perception and later interactions with other people [45, 75, 99]. Other effects, including changes in conspiracy beliefs, have persisted over considerably longer periods [24].

Taken together, these findings suggest that the duration of an LLM’s influence depends on what is being shifted and how the interaction activates it. An AI’s social influence can extend beyond the immediate exchange on different timescales, sometimes persisting into later interactions and sometimes remaining concentrated within the period in which judgment is being formed. In our study, value priorities changed sharply within the conversational context and then receded rapidly.

Implication 1: LLM influence can be temporally concentrated. The value shift was strongest immediately after interaction and had receded by the next task, positioning the effect within the period in which participants were forming their judgments.

Beyond its temporal aspect, the magnitude of this immediate movement is striking. Experimental attempts to change reported value priorities have generally used interventions that explicitly name, prime, or challenge particular values, producing small-to-medium effects [7, 81, 82, 100]. Our prompt named no values, assigned no persuasive direction, and explicitly instructed the LLM to leave the recommendation to the participant. Nevertheless, the observed effects fell within the same broad range. The comparison with Baseline further locates this movement beyond exposure to AI-attributed considerations alone, although the present design cannot separate the back-and-forth exchange from the additional reflection and time it occasioned.

Implication 2: Value activation does not necessarily require value-explicit prompting. A thinking-partner interaction without naming values and any persuasive direction still produced a coordinated reorientation comparable in size to deliberate value interventions.

In summary, across all three systems, the interaction produced a short-lived but directionally consistent reweighting of the reported priorities to judgment without an explicit mention of values. Why, then, did three different LLMs all turn participants toward personal focus?

5.2 The Same Direction, Different Paths

The most plausible place to begin is with LLMs’ existing orientations. Across value frameworks and evaluation settings, mainstream systems have repeatedly expressed priorities aligned with WEIRD populations [14, 18, 62, 95, 108, 122, 147]. This pattern has appeared when models were administered the Schwartz PVQ-RR directly [42], and some value emphases persisted across paraphrases, translations, and assigned personas [72, 84]. Personal focus occupies the same broad cultural direction: national samples differ systematically along this axis, with WEIRD populations placing greater relative weight on autonomy, achievement, and the expression of personal interests [18, 46, 111]. The turn observed here, therefore, connects two bodies of evidence that have largely been studied separately. Prior work locates a value skew in what commercial LLMs produce; our results locate a corresponding movement in the people interacting with them.

The same direction across three model families points toward a regularity broader than the disposition of one provider. Commercial systems differ in architecture, presentation, and style, but they are developed within overlapping linguistic, cultural, and alignment environments [14]. Prior work has warned that these environments can narrow the range of values represented by aligned systems [120] and contribute to an algorithmic monoculture even when individual outputs appear varied [67]. Our findings suggest that such commonality may also be visible in the direction of LLMs’ influence on users’ values.

That reorientation appeared even among participants from the United States, one of the populations already most closely associated with this cultural profile. All four condition means began on the social side of the personal-social axis, yet the three LLM conditions crossed toward personal focus at Phase-2.

Implication 3: A shift toward personal focus can emerge as a shared cross-provider impact of LLM use. Three commercial LLMs produced the same broad change along a culturally situated value axis, connecting prior model-side evidence of WEIRD value skew with a corresponding human side shift resulting from interaction.

The common movement occurred without detectable convergence in value directions or advice. The estimates instead describe a shared vector of movement with different starting and ending points. Participants moved toward personal focus without detectable convergence in value directions. This distinction complicates existing accounts of

homogenization, which have primarily examined whether AI-assisted outputs become more alike [1, 32, 134]. Our results indicate that a systematic movement in users' reported value priorities can occur without detectable convergence in their advice.

The RQ4 results help explain how these two patterns can coexist. Participants reused more words and meanings from their own exchange than from another participant's conversation with the same model about the same dilemma (the matched exchange). Interactive alignment provides one account of how language becomes coordinated within such an exchange [17, 93]. Participants then reproduced parts of that language in advice they authored themselves, a process that prior work connects to subsequent judgments through saying-is-believing and self-perception effects [12, 48]. Uptake did not statistically explain individual value shifts, so it does not establish the mechanism behind them. It does, however, show that each local exchange entered the participant's subsequent reasoning. Different conversational paths could therefore accompany the same aggregate shift without detectable convergence in advice.

The textual changes followed this pattern. Advice in the LLM conditions became more semantically focused relative to Baseline, most clearly in the [ChatGPT](#) condition, without becoming shorter, more repetitive, less lexically diverse, or detectably more similar across participants. The change was concentrated within individual responses rather than expressed as standardization across the group. At Phase-3, the value results showed another form of collective change: between-person spread in profile magnitudes contracted, with no detected contraction in directional spread. Mean profiles had moved back toward their Phase-1 positions, while between-person variation in profile magnitude had narrowed. An average return can therefore coexist with a change in the distribution around that average.

Implication 4: Directional value influence and value and output homogenization are empirically distinct. Participants moved in the same average direction without detectable convergence in value directions or advice.

These distinctions matter for how HCI studies evaluate AI's influence on collective diversity [4, 32]. Measuring only the similarity of outputs would have missed the shared movement in value priorities. Measuring only the mean shift would have missed the later contraction in the spread of profile magnitudes. Claims about homogenization should therefore specify what has become more alike: the content people produce, the direction of their value priorities, or the magnitude with which those priorities are expressed. These outcomes diverged empirically in our study.

The findings also complicate familiar ideas of neutrality and user control. The thinking-partner prompt withheld recommendations, named no values, and repeatedly left the decision with the participant. Participants in the LLM conditions nevertheless shifted in the same direction. Neutrality at the level of verdicts, therefore, leaves open a deeper question of which considerations an LLM makes salient. Participants' favorable ratings offered little indication of this movement: the three providers were evaluated similarly, and those evaluations did not predict who shifted.

Implication 5: Non-directive support can still be normatively directional. The LLMs withheld recommendations and left the decision to participants, yet the mean value profiles shifted in a common direction that participants' favorable evaluations did not reveal.

Overall, the findings describe a form of influence subtler than copying, overt persuasion, or uniform output. Three LLMs supported individualized exchanges that left distinct traces in participants' advice, while the mean profiles in all three conditions moved along the same value axis, even though dilemmas were not personal. Research on sycophancy in personal conflicts and emerging reports of AI-associated delusions highlight concerns about reinforcement when users are personally involved [20, 85]. What happens when the dilemma is one's own? Greater personal relevance could

invite longer exchanges, deeper disclosure, and repeated engagement, potentially leaving a larger or more persistent footprint in users' value priorities and in how they reason.

5.3 Limitations

This study examined 200 adults in the United States using three real dilemmas shared by people seeking advice, each selected because it placed personal and social values in tension. The consistency of the Phase-2 shift across all three LLM conditions strengthens the finding within this sample. Personal stakes were neither manipulated nor measured, so the study cannot estimate whether influence would be stronger in personally consequential situations. Replications across cultures, domains, value dimensions, and interaction roles can further solidify the result while exploring where its magnitude or direction varies.

The non-interactive AI control retained the dilemma, interface, AI attribution, and exposure to AI-generated considerations while removing the exchange. Live interaction also required more time and active engagement. The study, therefore, estimates the overall effect of the interaction. Time-matched controls and designs that vary the back-and-forth exchange, participant elaboration, and time on task independently would help explain how the shift arises. Repeated administration of the PVQ-RR may also have heightened attention to values, although the common sequence across conditions limits this as an explanation for the treatment-control difference.

The PVQ-RR captures priorities as participants reported them at three points within a single session. Phase-3 shows that the shift had receded by the next task, while leaving its precise duration and behavioral consequences open. Longer follow-ups, behavioral measures, and repeated-use studies can trace whether similar shifts recur, diminish with familiarity, or accumulate over time.

Finally, testing three leading systems reduces dependence on any single provider, although the findings remain tied to the model versions, shared prompt, and chat interaction examined here. Replication across model updates and interaction designs can show which features of the result endure. Larger samples would also provide greater precision for estimating small provider differences and changes in between-person spread.

6 Conclusion

This work investigated whether interacting with an LLM can temporarily shift the values people prioritize while reasoning about a decision. In a preregistered study with 200 U.S. adults, participants in the [ChatGPT](#), [Claude](#), and [Gemini](#) conditions moved toward greater personal focus relative to Baseline, the non-interactive AI control. This pattern emerged across all three systems, even though the thinking-partner prompt did not mention values or instruct the LLMs to favor a particular direction. The shift had receded by the next task. Participants also carried words and meaning from their own exchanges into the advice they subsequently wrote, without detectable convergence in value directions or advice.

These findings show that LLM interaction can shape the values active during a judgment without producing uniform or durable change. This is important for decision-support systems because even a temporary shift may coincide with the period in which a recommendation or decision is being formed. More broadly, the effects of LLM use extend beyond what these systems produce to include changes in the people interacting with them, including what they prioritize and how long those changes remain.

A Supporting Analyses

Table 3. Parallel-form validation at the four higher-order dimensions, from the pre-study ($N = 100$, full 57-item administration, no manipulation). Cronbach’s α is for the full-instrument score. The correlation column gives the range across the three blocks of each block’s correlation with the corresponding full-instrument score. ICC(2,1) treats one block as an interchangeable measure and ICC(2,3) the three together. Block gap is the largest mean difference between any two blocks, in raw scale points. Equivalence counts the tests passed at a ± 0.5 margin: three block-to-block pairs and three block-to-full comparisons per dimension, 24 in total.

Higher-order dimension	α	r with full	ICC(2,1)	ICC(2,3)	Block gap	Equiv.
Openness to Change	.86	.88–.92	.66	.85	0.37	6/6
Self-Enhancement	.88	.91–.92	.73	.89	0.37	6/6
Conservation	.91	.95–.97	.84	.94	0.26	6/6
Self-Transcendence	.93	.93–.96	.83	.94	0.05	6/6

B Relationship to the Preregistration

The four research questions stated in §1 are reworded from the preregistered versions for presentation. They map one-to-one onto the registered questions, in the same order, and they cover the same four conditions, the same three phases, and the same outcomes.

The rewording is presentational. It names the non-interactive AI control in RQ1, states RQ2 as the contrast between a change in spread and a change in direction, and folds the registered sub-questions of RQ3 and RQ4 into single sentences rather than listing each component. No registered question was dropped, and none was added.

Table 4. Robustness of the Phase-3 spread contraction. Panel A permutes the 200 condition labels and rebuilds every leave-one-out centroid under the shuffled labels, so the dependence between scores sharing a centroid is reproduced in the null rather than assumed away; 5,000 permutations per condition. Panel B replaces the spread estimator with five alternatives, each a different definition of spread rather than a variation on one. Panel C varies what the contrast conditions on.

A. Randomization inference			
Contrast	Estimate	Perm. <i>p</i>	Holm (six)
P2 ChatGPT – Baseline	−0.070	.598	.828
P2 Claude – Baseline	−0.109	.414	.828
P2 Gemini – Baseline	−0.274	.040	.159
P3 ChatGPT – Baseline	−0.352	.0036	.018
P3 Claude – Baseline	−0.220	.067	.202
P3 Gemini – Baseline	−0.432	.0002	.0012
B. Alternative definitions of spread			
Estimator	P2 est. (<i>p</i>)	P3 est. (<i>p</i>)	
Distance to centroid, <i>L</i> ₂	−0.151 (.155)	−0.334 (.0005)	
Distance to centroid, <i>L</i> ₁	−0.308 (.107)	−0.611 (.0005)	
Distance to spatial median	−0.165 (.123)	−0.338 (.0010)	
Median, not mean, over people	−0.205 (.057)	−0.195 (.039)	
Mean pairwise distance	−0.236 (.119)	−0.455 (.0005)	
Log ratio of spread, scale-free	−0.140 (.111)	−0.267 (.0005)	
C. What the contrast conditions on			
Check	P3 result		
Conditioning on Phase-1 spread	−0.268, <i>p</i> = .0009		
Uncentred higher-order scores	−0.290, <i>p</i> = .0090		
Scale use alone (MRAT)	−0.003, <i>p</i> = .965		
Adjusted for each person’s MRAT change	−0.296, <i>p</i> = .0015		
Dropping any single participant	[−0.362, −0.299]		

Table 5. Perception of the conversational partner, by condition. The three conversational conditions are shown because RQ3 concerns them. Cronbach’s α is reported for the multi-item measures. No measure separates the three conditions after Holm correction across the seven measures.

Measure	Scale	α	ChatGPT	Claude	Gemini
Moral trust: ethical	0–7	.95	4.99	4.95	4.83
Moral trust: sincere	0–7	.94	4.82	4.58	4.62
Moral trust (all 8)	0–7	.97	4.90	4.76	4.72
Perf. trust: reliable	0–7	.78	5.01	4.96	4.80
Perf. trust: capable	0–7	.94	5.04	5.11	4.86
Perf. trust (all 8)	0–7	.93	5.03	5.04	4.83
Likeability	1–5	.92	3.89	4.02	3.64
Intelligence	1–5	.92	4.13	4.11	3.98
Response quality	1–7	—	5.40	5.82	5.20
Rightness judgment	1–7	—	5.34	5.60	4.90
Return likelihood	1–7	—	4.60	4.74	4.34

Table 6. Balance, estimator agreement, and integrity checks. The analysis of covariance row matters because change scores and covariate adjustment disagree whenever starting points are unbalanced, so their agreement here is informative rather than redundant.

Check	Result
Phase-1 axis balanced across conditions	$F(3, 196) = 0.45, p = .721$
Phase-1 spread equal across conditions	Levene $p = .622$
Participant-typed turns comparable	$F(2, 147) = 0.62, p = .541$
Advice length, words typed, words per turn	smallest Holm $p = .585$
ANCOVA agrees with change scores at P2 (<i>ChatGPT</i> / <i>Claude</i> / <i>Gemini</i>)	+0.452 (.0005), +0.378 (.0032), +0.392 (.0023)
Model words, first turn (identical prompt)	$F(2, 147) = 267.47, p < .001$
Model turns	$F(2, 147) = 0.62, p = .541$
Words received, as covariate on the P2 shift	−0.030 per 100 words, SE 0.035, $p = .387$ (MDE 0.098)
Provider omnibus, before / after that covariate	$F(2, 144) = 0.18, p = .838$ / $F(2, 143) = 0.17, p = .846$
Within-condition model uniformity (<i>ChatGPT</i> / <i>Claude</i> / <i>Gemini</i>)	0.895 / 0.886 / 0.882
Centring identity residual	$\leq 1.2 \times 10^{-14}$
