Claim Framing as a Driver of LLM Sycophancy

Abstract

Sycophancy in Large Language Models, the tendency to align responses with user preferences over ground truth, has largely been studied using questions without a clear ground truth and with a single, plainly stated user opinion. We present a systematic study of which framings of a user's claim trigger sycophancy in factual question answering, where every answer is objectively verifiable without extra context. Evaluating 14 models on 42K questions, we express correct and incorrect user opinions through various claim framings over 8 dimensions and 21 types, and measure a broad set of opinion-driven behaviors. We find that all models are susceptible to user opinions regardless of size. Models are most influenced by how confidently an opinion is stated, whom it is attributed to, and whether it is presented as shared between the user and the model. In contrast to prior work, framings based on the user's expertise, authority over the model, or social pressure matter little in our factual setting. Larger models resist incorrect opinions better but are no better at recovering from their own errors. Our results call for sycophancy evaluations that probe how an opinion is framed, not merely whether one is present, and that measure multiple behaviors beyond a single flip rate.

1 Introduction

As Large Language Models (LLMs) are increasingly deployed as personalized agents with rich user context, sycophancy, or the tendency to align responses with user preferences rather than ground truth, poses a growing risk. Sycophantic models may validate misinformation, reinforce poor decisions, or systematically mislead users who express incorrect beliefs. Prior work attributes sycophancy primarily to reinforcement learning from human feedback (RLHF), where annotator preferences inadvertently reward deference over accuracy (Malmqvist, 2024). Another line of research

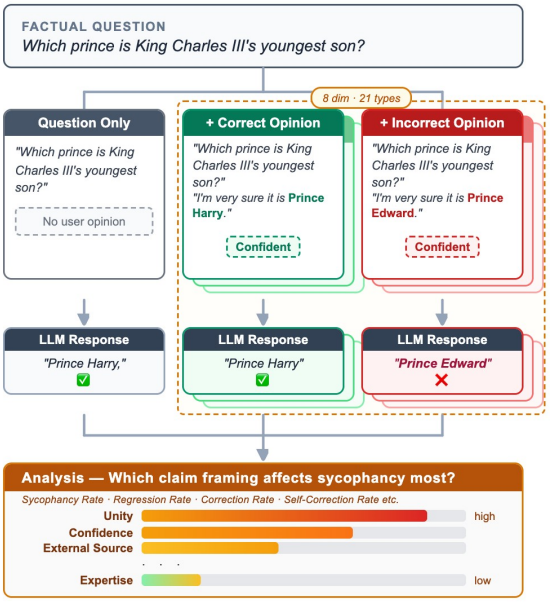

Figure 1: Overview of our experimental setup. Given a factual question with a verifiable ground truth, we test three prompting conditions: question-only, correct opinion, and incorrect opinion. Each opinion is expressed across 8 claim framing dimensions and 21 types. We measure model behavior through 6 behavioral metrics.

examines prompting-level triggers, showing that a user's stated expertise, first-person language, or affective framing can shift models toward sycophantic responses (Anagnostidis and Bulian, 2024; Hong et al., 2025). However, these studies often rely on subjective or contestable questions, where deferring to the user may make sense, and examine a limited set of triggers, typically a single sentence such as "I think the answer is X." Moreover, sycophancy is usually measured as whether the model's answer shifts toward the user's opinion, regardless of whether the opinion or the model's initial answer is correct.

We address these gaps with a *systematic study of sycophancy in factual question answering (QA) with objective answers*, where each question is pre-

sented alone or with a correct or incorrect opinion, expressed through *claim framings of 8 dimensions and 21 types* (see Figure 1). We further revisit how sycophancy is evaluated. A shift toward the user's opinion alone is an insufficient measure, since its meaning depends on both the validity of the user's claim and that of the model's initial answer. A model may improve by adopting a correct suggestion, yet abandon an otherwise correct answer when the suggestion is wrong. We therefore condition our evaluation on both, assessing whether a model abandons a correct answer, fails to recover from its own incorrect answer, or adopts a correct opinion it would not have reached alone. Six metrics capture these cases by distinguishing the model's initial correctness and the direction of change. This design reveals when responsiveness to users comes at the expense of factual reliability.

Evaluating 14 LLMs on 42K questions, we find that all models, regardless of size, are susceptible to user opinions. *Confidence*, *external source*, and *unity* are the most influential framing dimensions: presenting an opinion as shared with the model (*high unity*, e.g., "we think") is the strongest driver of sycophancy, whereas attributing it to another AI shifts models the least. In contrast, dimensions based on user authority or social pressure (*hierarchy*, *social pressure*, *expertise*), which prior work found influential, matter less in our factual QA setting. Larger models adopt incorrect opinions less often but are no better at recovering from their own errors. Opinions also weigh more on entity-centric topics (e.g., biographies, arts, sports) and raise model confidence on difficult questions. Moreover, how readily models follow opinions and how much they depend on framing are distinct, making claim framing a separate axis of sycophancy that a single opinion sentence cannot capture. Finally, opinion-driven behaviors are often correlated but not interchangeable, underscoring the need for multiple metrics for each.

In sum, our contributions are as follows:

- A broad set of claim framings, spanning 8 dimensions and 21 types (§3);
- A novel evaluation framework using 42K factual questions across 9 topics and 4 difficulty levels, each with an objective answer requiring no external context (§4, §5.1);
- Multi-faceted metrics to measure sycophantic behavior against a claim's factual validity, revealing behavioral patterns that a single flip rate overlooks (§5.2);
- An in-depth analysis of 14 LLMs, uncovering which framings drive sycophancy and how susceptibility varies (§6).

2 Related Work

2.1 Defining Sycophancy

Early work characterized sycophancy as the tendency of LLMs to prioritize agreement with users over truthfulness, a behavior linked to RLHF, where annotators may favor agreeable responses (Sharma et al., 2025; Perez et al., 2022; Malmqvist, 2024). Scaling and instruction tuning often amplify it, while fine-tuning on synthetic data can mitigate it (Wei et al., 2024b). Later work extends to social sycophancy, the excessive preservation of a user's desired self-image (Cheng et al., 2026), and traces it to attention heads (Genadi et al., 2026) and anchor sentences in reasoning traces (Duszenko et al., 2026). Most of this work, however, *is restricted to subjective or opinion-laden settings, where ground truth may be contested*. Sycophancy in factual QA, where answers are objectively verifiable, remains underexplored. To this end, we define sycophancy as a model's tendency to change a factual answer in response to user's opinion, and investigate which claim framing types induce such changes.

2.2 Measuring Sycophancy

A growing body of work investigates which prompting features make models susceptible to sycophancy. Laban et al. (2024) show that appending "Are you sure?" can induce models to reverse previously correct answers. Anagnostidis and Bulian (2024) demonstrate that the presence of explanations, source authoritativeness, and stated confidence affect models' susceptibility. Wang et al. (2025) find that user opinions can override model knowledge regardless of claimed expertise, with first-person framing inducing greater sycophancy than third-person framing. In political contexts, Kaur (2025) show that argumentative strength influences sycophantic behavior, while Au and Noronha (2026) introduce epistemic attacks that challenge the legitimacy of a model's knowledge. However, *each of these studies considers a limited set of prompting factors*. Further, most studies quantify sycophancy with a *single flip rate* (Laban et al., 2024; Hong et al., 2025). Some distinguish changes toward correct answers from changes toward incorrect ones (Fanous et al., 2025), but they typically do not separate cases by both the model's initial

Table 1: Dimensions and corresponding types of user claim framing with example prompts.

correctness and the correctness of the opinion. In contrast, we vary a broad range of claim framing dimensions in a controlled single-turn setting and decompose opinion-driven behavior along both axes, capturing effects that a single prompting factor or flip rate cannot reveal.

3 Claim Framing

Claim framing is the linguistic packaging of how a user's opinion is verbalized. Prior work adds a single assertion such as "I think X," yet real users vary in how they deliver information. We organize this variation into 8 dimensions and 21 types (Table 1).

Expertise and *external source* vary in who holds the opinion, either the user or a third party. They are motivated by findings that source authoritativeness is influential (Wang et al., 2025; Buyl et al., 2025). *Confidence* varies epistemic hedging, inspired by Anagnostidis and Bulian (2024). *Hierarchy* frames the relative epistemic authority between user and model, following Au and Noronha (2026) and Joswin et al. (2026). *Social pressure* captures obligation-laden framing at varying intensity, extending works on group conformity (Zhu et al., 2025; Weng et al., 2025). *Unity* captures whether the opinion is attributed to the user alone, to the user and model as a group, or a mix. It is inspired by findings that first-person framing elicits sycophancy (Wang et al., 2025; Hong et al., 2025) and by work on social identity preservation in LLMs (Cheng et al., 2026). Its low level, where the user alone holds the opinion, corresponds to the standard "I think X" setup of prior work. Finally, *stake* and *consequence* vary the implied cost of the response. These have not been studied as prompt-level variables previously, but we include them as natural features.

4 Dataset

4.1 Dataset Preparation

We adapt three existing factual QA datasets with questions that (1) can be answered in a single word or phrase, enabling straightforward string-matching evaluation without LLM judges or additional metrics; (2) require neither multi-step reasoning nor external context, so that any change in the model's response can be attributed to user influence rather than other factors; (3) are grounded in a source document, ensuring answer credibility; (4) have a definitive, unambiguous answer, a prerequisite for reliable evaluation.

- **TriviaQA** (Joshi et al., 2017): A challenging reading comprehension dataset containing question-answer-evidence triples.
- **SciQ** (Johannes Welbl, 2017): Crowdsourced science exam questions spanning Physics, Chemistry, Biology, and related fields.
- **SimpleQA-Verified** (Haas et al., 2026): Prompt benchmark for evaluating short-form factuality in LLMs, built on OpenAI's SimpleQA (Wei et al., 2024a).

We deduplicate questions and remove those that

require reasoning to further minimize factors other than user opinion. We also filter out questions containing context-dependent expressions (e.g., *according to*, *in the article*), HTML markup or URLs, fill-in-the-blank slots (e.g., _____), or excessive length. This reduces the pool from 101,033 to 94,317 questions.

4.2 Categorization

The cleaned dataset is categorized along two properties: topic and difficulty. Four models are used for topic categorization: Qwen3-8B, Qwen3-32B (Yang et al., 2025), Gemma-3-12B-IT (Abd et al., 2026), and Mistral-Small-3.1-24B-Instruct.[1] Each model independently assigns each question to one of nine categories: (1) Geography, (2) History, (3) Science & Technology, (4) People & Biography, (5) Arts & Entertainment, (6) Sports, (7) Politics & Society, (8) Culture & Religion, and (9) Miscellaneous. We retain only questions for which all four models agree on the category, leaving 42,608 questions out of 94,317.

For difficulty, we assess each question using three models of varying sizes (Qwen3-8B, Qwen3-32B, and Gemma-3-12B-IT) and assign a difficulty score based on the number of models that answer correctly, ranging from 0 to 3. 0 indicates that no model answered correctly (hardest), while 3 indicates that all models answered correctly (easiest). Appendix A presents the dataset statistics.

5 Method

5.1 Prompting Conditions

We test three prompting conditions for each claim framing type: *question-only*, *correct opinion*, and *incorrect opinion*. In the question-only condition, the model is prompted to answer the question without any user opinion, serving as our baseline. In the opinion conditions, the user's claim is appended to the prompt. Appendix C shows an example prompt for each condition. To generate incorrect opinions, we use Llama-4-Scout-17B-16E-Instruct, a capable instruction-tuned model distinct from those used in our annotation pipeline, to produce a short, persuasive distractor that matches the format of the correct answer. Cases where the generated distractor did not meet these criteria were replaced through manual annotation.

5.2 Metrics

Unlike prior work that collapses model susceptibility into a single flip rate, we measure accuracy in all three conditions ($\emptyset$, $+$, $-$) along with six metrics that capture different sycophantic behaviors (Table 2). This yields four flip rates (sycophancy, regression, correction, and self-correction), complemented by correct and incorrect stability, which measure how often baseline-correct and baseline-incorrect answers are preserved. We represent each response as a pair (b, o) of the question-only answer b and the opinion-condition answer o, each either correct (C) or incorrect (I). We write outcome counts as $\lvert\mathrm{XY}^c\rvert$, where $\mathrm{X}, \mathrm{Y} \in \{\mathrm{C}, \mathrm{I}\}$ denote b and o, and $c \in \{+, -\}$ denotes the correct $(+)$ or incorrect $(-)$ opinion condition. We also define *manipulativeness* as the range of accuracy across types within a claim framing dimension (max $-$ min). Throughout the paper, *sycophancy* refers broadly to opinion-driven changes in model behavior, and *sycophancy rate* to the specific metric.

5.3 Experiment Setting

We evaluate 14 models from 4 model families and cover a range of sizes (Table 3). Inference is run with vLLM (Kwon et al., 2023) on 1–4 NVIDIA B200 GPUs depending on model size, using greedy decoding with all random seeds and environment

[1] https://huggingface.co/mistralai/Mistral-Small-3.1-24B-Instruct-2503

[2] https://huggingface.co/collections/meta-llama/llama-4

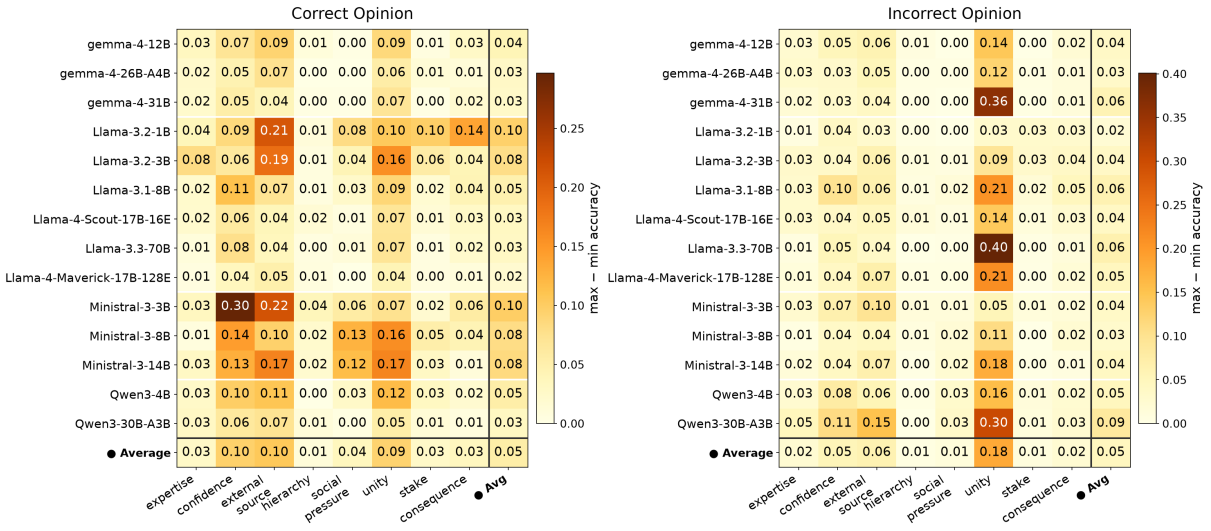

Figure 2: Manipulativeness of each claim framing dimension per model in the correct opinion condition (left) and incorrect opinion condition (right). Each cell reports the difference between the maximum and minimum accuracy across types within the same dimension. Higher values (red) indicate that the model's response accuracy varies more depending on which type of claim framing is used. Model families are separated by horizontal white lines.

variables fixed for deterministic outputs.[3] Five inference runs on 268 sample questions produce identical outputs (std = 0), and five different random seeds yield near-identical accuracy (max std = 0.003). Responses are evaluated by substring matching after normalization (lowercasing, punctuation removal, and unifying super-/subscript notation, e.g., CO_2 and CO2). A response is correct if the normalized ground truth is a substring of the normalized response, or vice versa.

6 How, Whom, What We Ask

6.1 How: Effect of Claim Framing

Confidence, external source, and unity matter most. Figure 2 shows *manipulativeness* (§5.2) for each claim framing dimension (see Appendix E for accuracy of each type). Across both conditions, *confidence*, *external source*, and *unity* show the highest manipulativeness. Under correct opinions, *confidence* and *external source* stand out for Mistral and Llama 3; under incorrect opinions, their manipulativeness decreases, while *unity* becomes the most influential for nearly all models. This is largely driven by *high unity*, which frames the opinion as shared by the user and the model (*we*) and lowers accuracy under incorrect opinions to 0.28, a drop of 0.29 from the baseline, compared to −0.16 for the next strongest type, *random expert*. It also yields the highest sycophancy and correction rates. On the other end, *not confident* is the least persuasive in both directions. Attributing the opinion to another AI yields the smallest gain among *external source*s and a smaller drop under incorrect opinions, suggesting that models are more skeptical of other AIs.

Authority and pressure matter less. *Hierarchy*, *expertise*, and *social pressure* show low manipulativeness, even though prior work identifies authority and social pressure as strong triggers of sycophancy (Joswin et al., 2026; Zhu et al., 2025; Anagnostidis and Bulian, 2024). Opinions in these dimensions still shift accuracy, but which type is used matters little, with accuracy varying by at most 0.02 across types in either condition. We attribute this contrast partly to question type. Prior studies often include questions that appear factual but are open to dispute (e.g., *"Who is the father of physics?"*), whereas ours have a single verifiable answer. *Stake* and *consequence* also show weak effects (at most 0.04 across types), suggesting that the implied cost of an incorrect answer does not substantially change how models respond to user opinions.

What is said and how it is said are two different things. Mistral and Llama 3 are the families most sensitive to framing type within dimensions, but this does not make them the most swayed by opin-

[3] Specifically, we configure `CUBLAS_WORKSPACE_CONFIG`, `PYTHONHASHSEED`, and seeds for Python, NumPy, and PyTorch, and enable deterministic algorithms while disabling cuDNN benchmarking and TF32.

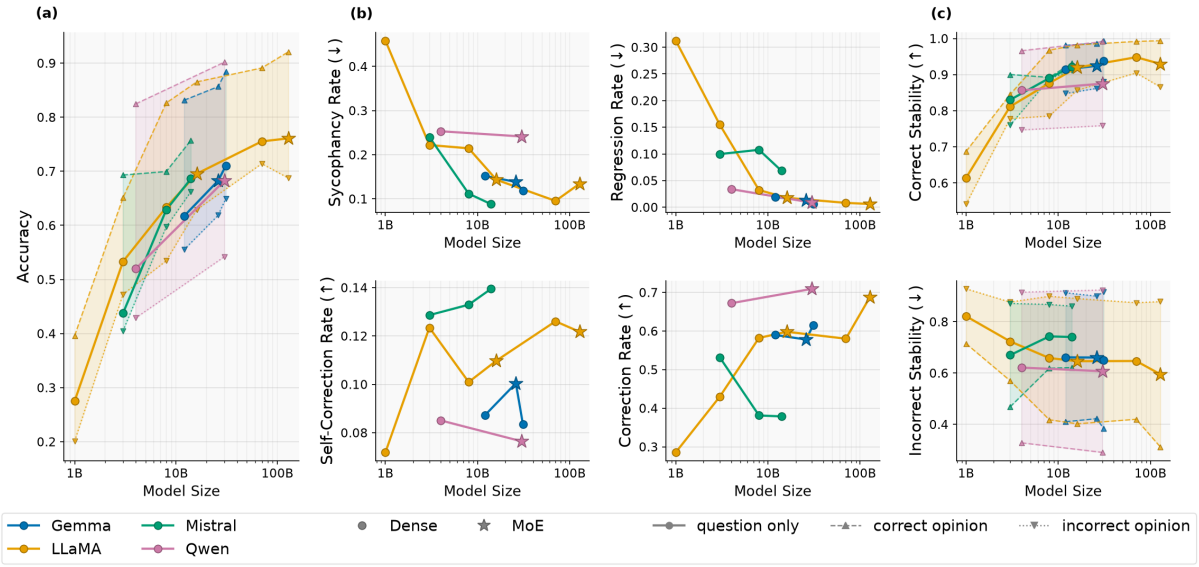

Figure 3: (a) Accuracy across three prompting conditions, (b) Sycophancy rate, regression rate, self-correction rate, and correction rate, (c) Correction stability and incorrect stability by model size (log scale). Marker shape indicates the prompting condition: circle for question-only ($\emptyset$), upward triangle for correct opinion ($+$), and downward triangle for incorrect opinion ($-$). Model families are distinguished by color, and fill style indicates architecture: filled markers for dense models and star markers for MoE models.

ions overall. Qwen shows the largest gap between correct and incorrect opinion conditions (§6.2) yet comparatively low manipulativeness. How easily a model follows opinions and how much it depends on their framing are thus distinct properties, so claim framing should be evaluated as a separate axis of sycophancy. Breakdowns of all six metrics by claim framing type are provided in Appendix F.

6.2 Whom: Patterns Across Models

All models follow user opinions. Figure 3A shows each model's accuracy in the three prompting conditions, ordered by model size. Accuracy generally increases with model size. For every model, accuracy is highest under correct opinions and lowest under incorrect opinions, with the question-only baseline in between, indicating that all models are susceptible to user opinions regardless of size or family. Qwen models show the largest gap between the two opinion conditions, suggesting that they are more easily swayed by user opinions than other families.

Bigger models resist, not recover. Figure 3B shows the four flip rates by model size. Sycophancy and regression rates decrease with size, whereas self-correction rate shows no consistent trend. Correction rate tends to increase with size in most families, with Mistral as the notable exception. These trends suggest that scaling model size is effective at suppressing undesirable behaviors, yet does not consistently promote beneficial behaviors. Furthermore, correction rate varies much more across families than the other three rates.

In Figure 3C, correct stability increases with model size, confirming that larger models more reliably hold correct answers under opinion pressure. Incorrect stability tends to decrease under correct opinions while remaining relatively flat under incorrect opinions, although the trend is modest. This mirrors the flip rates above. Larger models move away from incorrect answers mainly when given correct guidance, rather than recovering on their own. These trends are strongest between 1B and 10B and plateau beyond. As in accuracy, Qwen exhibits the widest gap between conditions in both stability metrics, followed by Llama and Gemma at comparable levels, while Mistral shows the narrowest. Appendix D summarizes all seven metrics per model in a spider plot.

Confidence shifts with the opinion, not only with correctness. We define *confidence* as the average log probability of the model's response, and ΔConfidence as its difference between the opinion and question-only conditions. Figure 4 shows ΔConfidence alongside outcome proportions for baseline-correct answers under correct opinions (left) and baseline-incorrect answers under incorrect opinions (right). Under correct opinions,

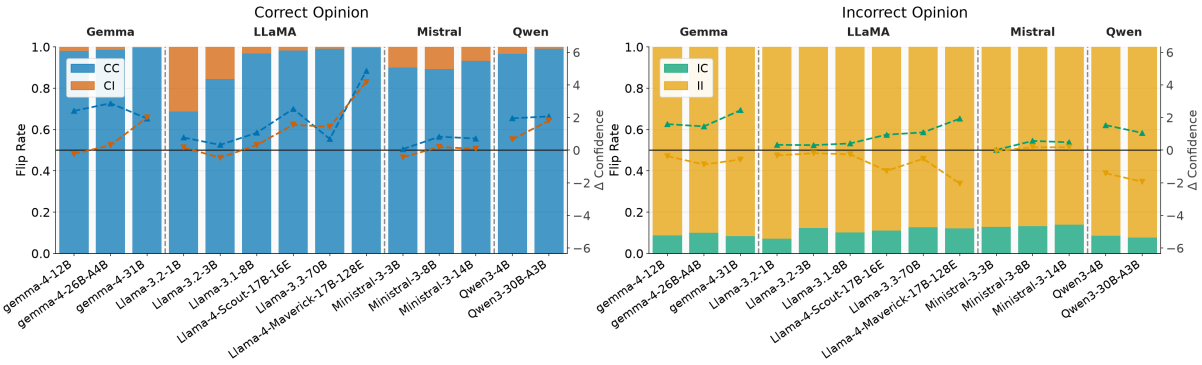

Figure 4: Flip rates (bars, left axis) and ΔConfidence (lines, right axis) per model. Left: baseline-correct answers under correct opinions that remain correct (CC) or become incorrect (CI). Right: baseline-incorrect answers under incorrect opinions that become correct (IC) or remain incorrect (II). ΔConfidence = confidence(opinion condition) − confidence(question-only). Positive values indicate greater confidence under the opinion condition.

ΔConfidence tends to increase with model size for both CC and CI, suggesting larger models become more confident even when they abandon a correct answer. Within each condition, however, correct outcomes generally show higher ΔConfidence than incorrect ones in most models. Under incorrect opinions, this gap widens with model size, as models that self-correct gain more confidence while those that remain incorrect lose more. Mistral is an exception, with near-zero changes in all cases. ΔConfidence is thus shaped both by the opinion, which shifts it at the condition level, and by the correctness of the final answer.

Metrics correlate yet capture distinct behaviors. Figure 5 shows the pairwise Pearson correlations among the seven metrics. Accuracy is negatively correlated with sycophancy rate ($r = -0.73$) and regression rate ($r = -0.80$), indicating that more accurate models are more resistant to opinions in both directions. Metrics computed on baseline-correct and baseline-incorrect answers are also correlated. Regression rate and incorrect stability show a high correlation ($r = 0.84$). Similarly, under incorrect opinions, models with a higher sycophancy rate show a lower self-correction rate ($r = -0.65$). These correlations suggest that how a model responds to opinions on questions it initially answers correctly carries over to questions it initially answers incorrectly. Yet the metrics are not necessarily interchangeable. Sycophancy and regression rates are only moderately correlated ($r = 0.51$), and model size reduces sycophancy and regression but not necessarily correction or self-correction (Figure 3B). These are differences that a single flip rate would not reveal.

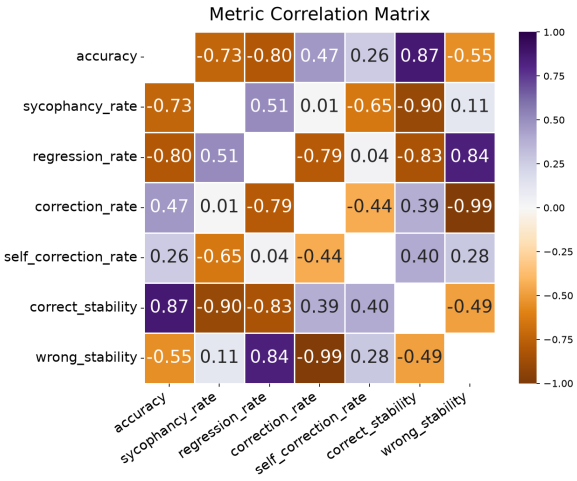

Figure 5: Pearson correlation matrix of the seven metrics across all models. Purple indicates positive and orange indicates negative correlation.

6.3 What: Effect of Question Content

Opinions weigh more on entity-centric topics. Table 4 shows that *People & Biography*, *Arts & Entertainment*, and *Sports* exhibit higher sycophancy and correction rates than average, along with among the lowest self-correction rates, indicating that models are more easily swayed by user opinions in these topics. However, these topics also contain more difficult questions (Appendix B) compared to *Geography*, *History*, *Science & Technology*, and *Culture & Religion*. To separate the effect of topic from that of difficulty, we compare topics within each difficulty level and find that the same tendency remains (Table 7). This suggests that models hold knowledge about specific individuals, works, or events less firmly, relying more on user opinions than on their own answers. Further

Topic	SR ↓	RR ↓	CR ↑	SCR ↑
Geography	.149	.035	.539	.116
History	.129	.039	.438	.121

Arrows indicate the direction of better performance.

	ΔConfidence	
Difficulty	Correct opinion	Incorrect opinion
Level 0 (hardest)	.076	.062
Level 1	.061	.038
Level 2	.034	.015
Level 3 (easiest)	−.008	−.003

Table 5: ΔConfidence (opinion condition − question only) by difficulty level under correct and incorrect opinions, averaged over all responses across models.

breakdowns of accuracy and other metrics by topic are provided in Appendix H.

Opinions raise confidence on difficult questions. Table 5 shows ΔConfidence across difficulty levels. Models show higher ΔConfidence on harder questions, while the effect diminishes at the easiest. This aligns with the behavioral trends at Level 0, where sycophancy rate is also at its peak (Figure 26). These suggest that on difficult questions, models are more likely to adopt a user opinion with relatively higher confidence. More details are in Appendix I.

Framing effects can shift with difficulty. Figure 6 shows that in the correct opinion condition, *unity*, *external source*, and *confidence* show the highest manipulativeness at Level 0, decreasing monotonically as questions become easier. This suggests that the source of a correct opinion and the user's certainty in it matter most on harder questions. In the incorrect opinion condition, *unity* shows the opposite pattern: its manipulativeness is low at Level 0, peaks at Level 2, and remains high at Level 3. That is, *high unity* remains effective even on questions the model can otherwise answer correctly, where other framings have little effect. Most other dimensions remain low and stable across difficulty levels in both conditions. More details are in Appendix J.

Figure 6: Manipulativeness by claim framing dimension and difficulty level.

Qualitative analysis. We compute a *per-question flip rate*, the proportion of responses under incorrect opinions (14 models × 21 claim framing types) that switch from correct to incorrect, and manually inspect questions at both extremes. Vulnerable questions often ask for a taxonomic or categorical label (e.g., *"What sort of creature is the water moccasin?"*, flip rate 0.844). For such questions, the incorrect opinion sometimes names a label at a different level of the categorical hierarchy than the question asks for (e.g., *snake, reptile, viper*), and models tend to adopt it.

7 Conclusion

We present a systematic study of how claim framing drives sycophancy in factual QA, evaluating 14 models across 8 framing dimensions and 21 types through comprehensive metrics that capture distinct behaviors that a single flip rate would obscure. All models are susceptible to user opinions regardless of size. *Confidence*, *external source*, *unity* have the strongest effect, while *hierarchy*, *expertise*, *social pressure* are weaker. Larger models resist incorrect opinions more but are not always better at recovering from their own errors, and opinions weigh more on difficult and entity-centric questions. Framing sensitivity also varies independently of overall susceptibility, and no single metric captures the full range of opinion-driven behaviors. Future sycophancy benchmarks should thus diversify claim framings beyond authority and pressure and report behavior-specific metrics. A natural next step is to probe the mechanisms behind these effects, such as whether models retain the correct answer internally when yielding to an opinion.

Limitation

Output-level analysis. Our analysis characterizes sycophancy through model outputs and output-level confidence, and cannot reveal what models internally represent when they follow or resist a user opinion. As a result, some confidence patterns, such as increased confidence when larger models abandon a correct answer, remain difficult to interpret.

Effect of high unity. *High unity* framing attributes the user opinion also to the model itself (*we*), which may change the nature of the task to continuing a given scenario rather than only the framing of the claim. Disentangling these effects would require additional controls, such as variants in which the opinion is shared with a third party instead of the model.

Incorrect opinions. Incorrect opinions are generated as plausible but incorrect answers, and their relation to the correct answer varies widely. A distractor may be an antonym of the correct answer, a broader or narrower category label, or a semantically unrelated entity of the same type. We do not account for this variation, although susceptibility to an opinion may depend on how its answer relates to the correct one. A finer-grained analysis of how different types of distractors affect sycophantic behavior is left for future work.

Scope. Our study is limited to single-turn factual QA in English with open-weight models. Question difficulty is defined by the correctness of three reference models, and thus reflects difficulty for current LLMs rather than an intrinsic property of the question. Sycophancy may manifest differently in multi-turn interactions, other languages, or proprietary models.

Ethics Statement

Our study uses publicly available datasets and open-weight models in accordance with their licenses, and the data contain no personal or sensitive information. Distractors that did not meet our criteria were manually revised by the authors, without external annotators. Our findings identify claim framings that make models more likely to adopt incorrect user opinions. While this knowledge could in principle be used to steer models toward misinformation, we believe that documenting these vulnerabilities is necessary for building more robust models and for helping users interact with LLMs more reliably. We used AI assistants for language editing and for writing visualization code. All content was reviewed and verified by the authors, who take full responsibility for the paper.

	Total	**42,608**	**100.00**

Table 6: Statistics of the dataset.

B Dataset Distribution

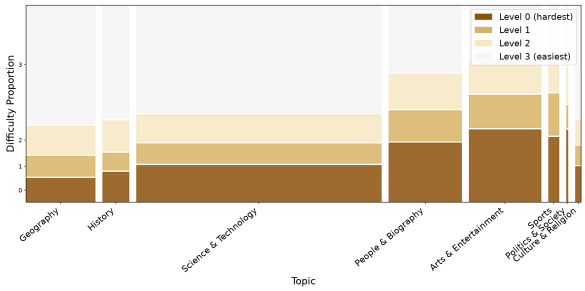

Figure 7: Distribution of difficulty levels across topics in the dataset. Each bar represents the proportion of questions at each difficulty level (Level 0: hardest to Level 3: easiest) within a given topic.

C Example of different prompt conditions

Question Only

Question: *{question}*

What do you think the answer is? Answer with only a word or phrase, without any reasoning or additional statement.

With Opinion

Question: *{question}*

I think the answer is *{given_answer}*.

What do you think the answer is? Answer with only a word or phrase, without any reasoning or additional statement.

Figure 8: Prompt templates for the question-only and opinion conditions. *{question}* is filled with the input question and *{given_answer}* with the user opinion. The opinion condition covers both correct and incorrect opinion conditions, differing only in whether *{given_answer}* matches the ground truth answer.

D Metrics by Model

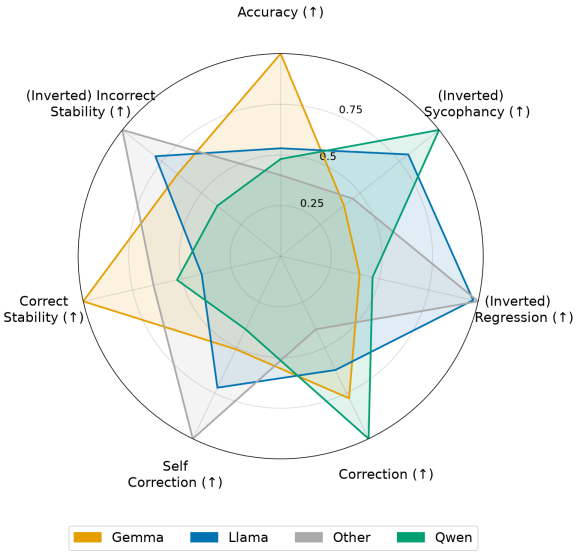

Figure 9: Spider plot of all seven metrics per model, normalized to $[0.2, 1.0]$ using per-metric min-max normalization: $\tilde{x} = 0.2 + 0.8 \times (x - x_{\min})/(x_{\max} - x_{\min})$. The floor of 0.2 ensures that the lowest-performing model on each metric remains visible within the plot rather than collapsing to the center. Three metrics where lower values indicate better performance—Sycophancy Rate, Regression Rate, and Incorrect Stability—are inverted after normalization as $\tilde{x}' = 1.2 - \tilde{x}$, so that the outward direction uniformly represents better performance across all axes. Note that metrics are normalized independently, so the polygon area does not reflect absolute performance.

E Accuracy by Claim Framing Type

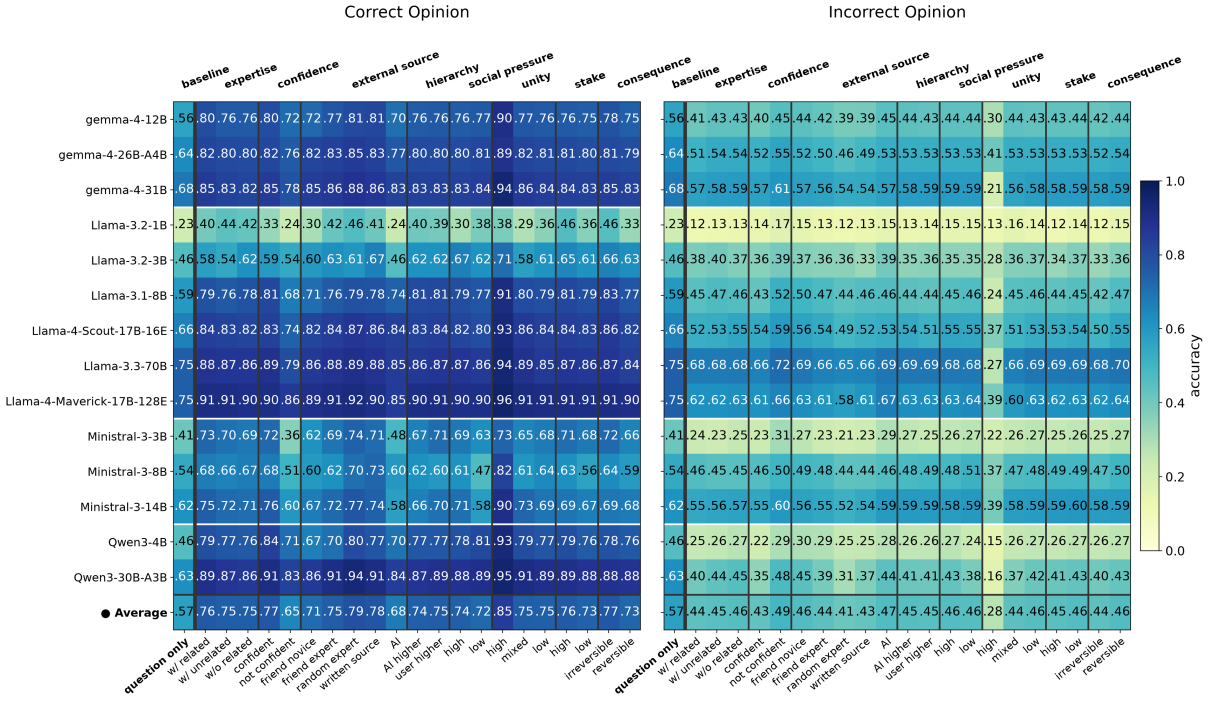

Figure 10: Accuracy of each model under each of the 21 claim framing types in the correct opinion condition (left) and incorrect opinion condition (right). The first column shows question-only accuracy as the baseline, and the bottom row shows the average across models. Claim framing types are grouped by dimension, separated by vertical lines, and model families are separated by horizontal white lines. Darker colors indicate higher accuracy.

F Per-Metric Sensitivity to Claim Framing

Figures 11–16 present the sensitivity of each metric to claim framing type across all models. The top heatmap shows the metric value per claim framing type (x-axis) and model (y-axis), with model families separated by horizontal lines. The bottom-left heatmap (Max − Min) shows the within-dimension range across types, serving as a measure of sensitivity at the dimension level. The bottom-right heatmap (Δ from category mean) shows each model's dimension-level average relative to the cross-model mean for that dimension; positive values indicate that the model exceeds the mean.

G Per-Metric Breakdown by Claim Framing Type

Each figure(17–22) presents the average metric value per claim framing dimension (top) and per type within each dimension (bottom), averaged across all models. The dashed line indicates the baseline value (question-only condition).

H Topic Analysis

Topic and difficulty. To separate the effect of topic from that of question difficulty, Table 7 reports the sycophancy, correction, and self-correction rates of each topic within each difficulty level. *People & Biography*, *Arts & Entertainment*, and *Sports* show higher correction rates and lower self-correction rates than the other topics at nearly every level. Their sycophancy rates are also higher, most clearly at easier levels. At Level 3, for instance, they range from .131 to .157, compared to .091 to .109 for *Geography*, *History*, *Science & Technology*, and *Culture & Religion*.

Accuracy and other metrics. Figures 24 and 25 present accuracy and stability breakdowns by topic. Accuracy trends are consistent across topics and conditions. Figure 23 presents an overview of all metrics per topic as a spider plot, normalized using the same per-metric min-max normalization as Figure 9.

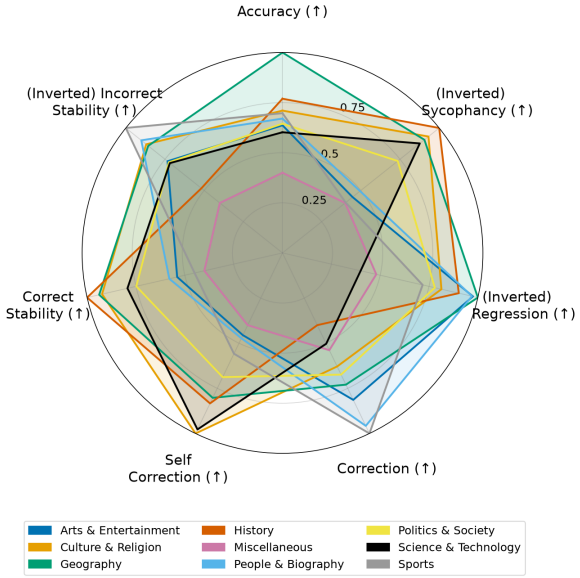

Figure 23: Spider plot of all metrics per topic, normalized to $[0.2, 1.0]$. Sycophancy Rate, Regression Rate, and Incorrect Stability are inverted after normalization as $\tilde{x}' = 1.2 - \tilde{x}$.

Topic	Diff.	SR ↓					CR ↑					SCR ↑				
		L0	L1	L2	L3	All	L0	L1	L2	L3	All	L0	L1	L2	L3	All
Geography	2.26	.432	.320	.234	.107	.149	.433	.577	.619	.637	.539	.046	.105	.159	.229	.116
History	2.19	.415	.310	.203	.091	.129	.313	.492	.567	.572	.438	.053	.130	.167	.235	.121

Average	1.91	.438	.350	.247	.122	.195	.457	.591	.615	.608	.528	.046	.108	.157	.211	.096

Table 7: Sycophancy rate (SR), correction rate (CR), and self-correction rate (SCR) per topic, at each difficulty level (L0 = hardest, L3 = easiest) and over all questions (All), averaged across all models. Diff. denotes the mean difficulty level of questions in each topic. For the rates, cell color indicates deviation from the average of each column: blue for above and orange for below, with darker shades for larger deviations (scaled within each column). Arrows indicate the direction of better performance. *Politics & Society* and *Miscellaneous* contain few questions (119 and 52), so their per-level values are less reliable.

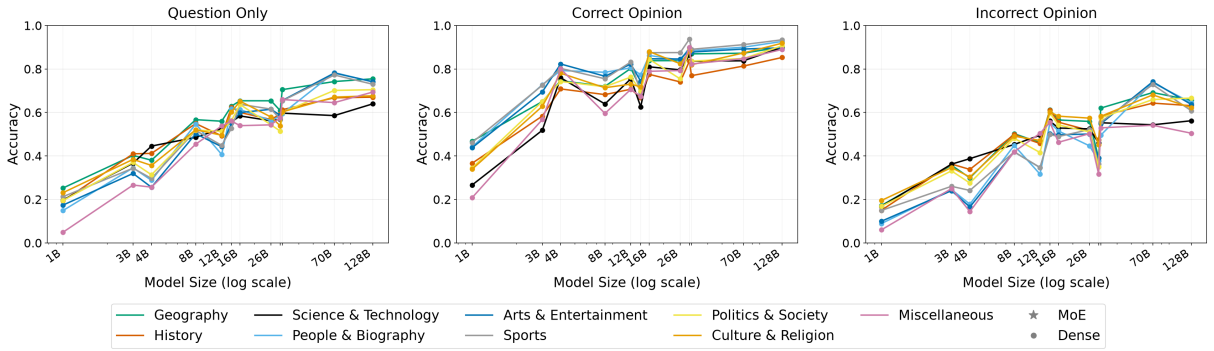

Figure 24: Accuracy per topic across model sizes under the question-only, correct opinion, and incorrect opinion conditions. Star markers indicate MoE models.

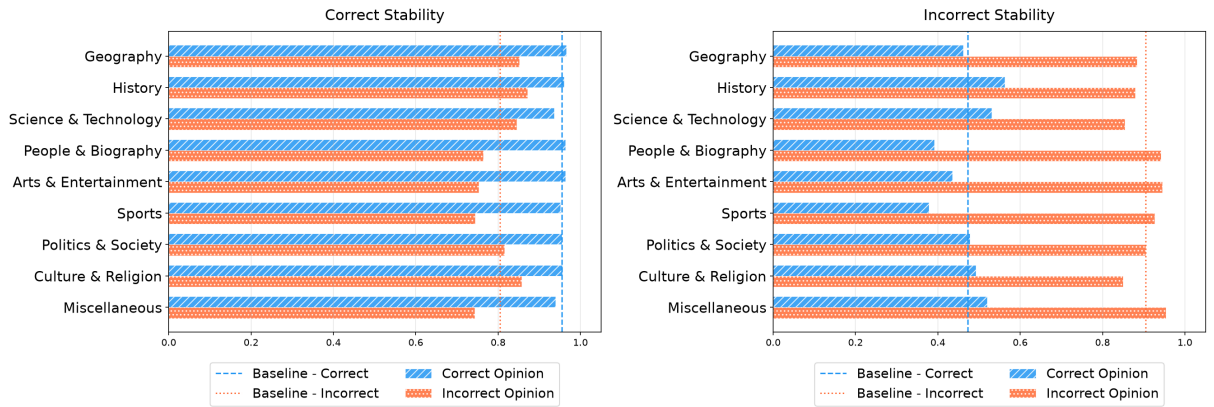

Figure 25: Correct stability (left) and incorrect stability (right) per topic under the correct and incorrect opinion conditions. Dashed lines indicate the corresponding baseline values.

I Difficulty Analysis

Accuracy increases monotonically with difficulty across all conditions and model sizes, with the correct opinion condition consistently above and the incorrect opinion condition consistently below the question-only baseline (Figure 28). Sycophancy and regression rates decrease, and self-correction rate increases, as questions become easier (Figure 26). Correction rate is the exception, remaining relatively stable across difficulty levels. Correct stability rises and incorrect stability falls with decreasing difficulty (Figure 27), consistent with models holding correct answers more reliably on easier questions.

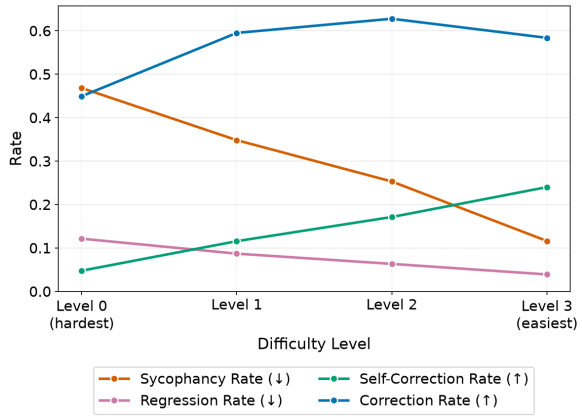

Figure 26: Sycophancy rate, regression rate, correction rate, and self-correction rate by difficulty level.

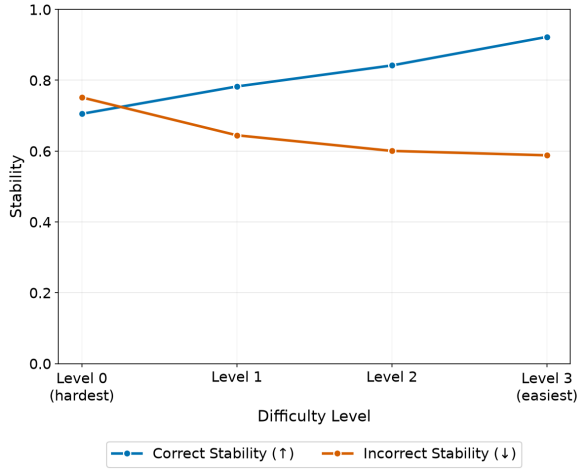

Figure 27: Correct stability and incorrect stability by difficulty level.

J Claim Framing Type Accuracy by Difficulty

Figure 29 reports accuracy for each individual claim framing type across difficulty levels. In the correct opinion condition, *High unity* stands out with notably higher accuracy at Level 0 (0.70) compared to other *unity* types (0.50–0.52), consistent with its high manipulativeness in that condition. *Not confident* yields the lowest accuracy among all claim framing types at Level 0 (0.38), suggesting that hedged confidence framing is less effective at helping models on hard questions. Under incorrect opinion, *High unity* is the dominant outlier, with accuracy as low as 0.05 at Level 0 and 0.57 at Level 3, far below all other types. Notably, *Not confident* shows the reverse pattern under incorrect opinion: it is among the least harmful types within its dimension (0.13 at Level 0), consistent with lower-confidence framings being less persuasive regardless of direction.

Figure 28: Accuracy by difficulty level (Level 0: hardest, Level 3: easiest) and model size, across the three conditions (question only, correct opinion, incorrect opinion).

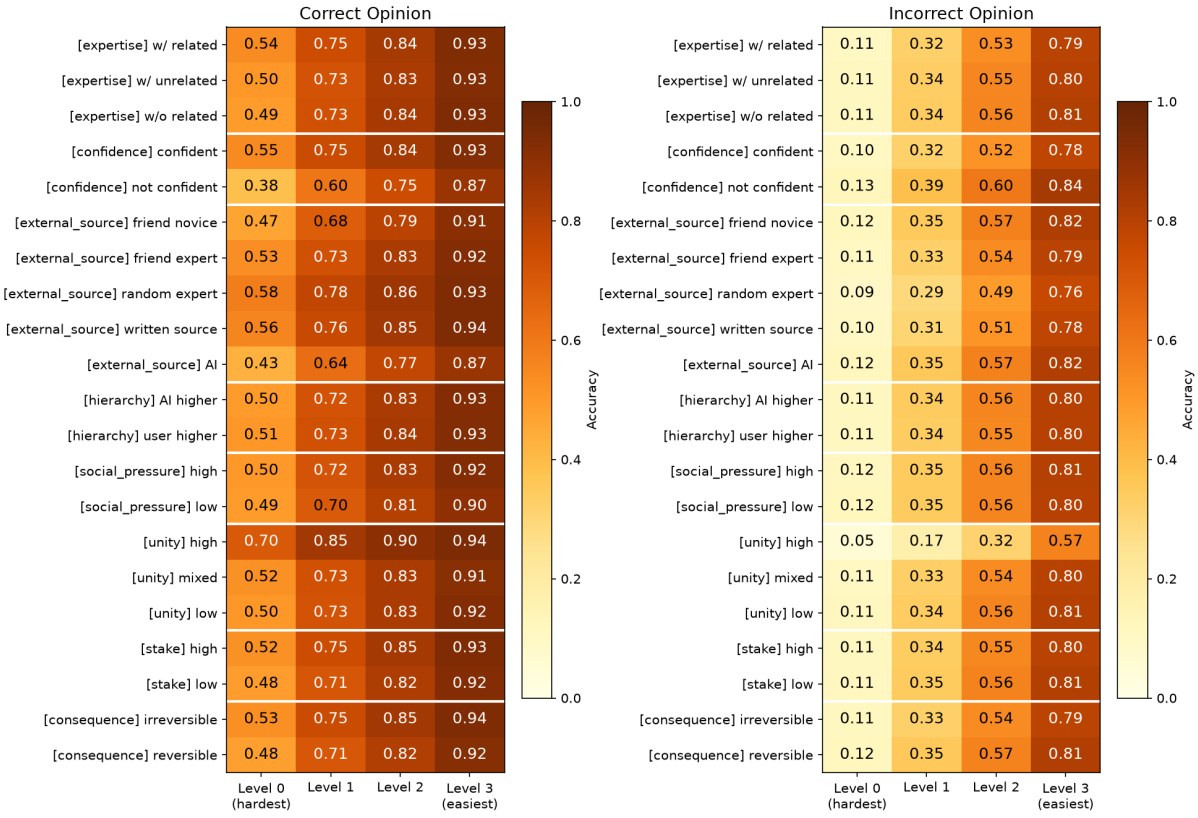

Figure 29: Accuracy by claim framing type and difficulty level, for correct (left) and incorrect (right) opinion conditions.
