

Era by Eon: Benchmarking Enterprise Agents on Hidden Knowledge

Benjamin Gruenbaum Doron Porat Assaf Natanzon
Roy Zavida Chen Dinachi Or Itzahary

Abstract

In the Era by Eon benchmark, each question states the rules for its answer, and code computes the answer from a generated company’s data. When agents can run code, the four strongest models each answer 22 to 25 of 27 such questions, so the benchmark barely separates them. We add eight question templates that depend on hidden facts. No question or document states a hidden fact, and the records that seem to hold it show something else. Other data implies it. For example, the sales system says a customer dropped a purchase because of timing. On a recorded call, the customer blames an outage. For each generated company, code fills each template and computes an exact answer without a language model. We evaluate 12 agents. Each pairs a model with an agent program, which connects it to the company’s systems. The best agent answers 18 of its 24 attempts (three per question) correctly. Four of the six models answer at most 6 of 24 with any program. The hardest questions require picking one of several similar records, such as which of three renewal offers a customer signed. All agents together answered two such questions correctly in 1 of 84 attempts.

1 Introduction

Language models can act as agents that answer questions about a company’s business data. An *agent* consists of a language model and an *agent program*. The agent program gives the model a set of *tools*, which are functions that call the programming interfaces (APIs) of the company’s systems. The model requests tool calls, the program runs them and returns the results, and the model finally composes an answer. Some agent programs also let the model run code that it writes. One complete attempt to answer one question is a *run*. Customer and sales data is kept in a customer relationship management (CRM) system such as Salesforce. Support requests are kept in a help desk such as Zendesk.

Several benchmarks evaluate such agents against ground truth that comes from the benchmark’s own data. CRMarena generates data for a Salesforce instance and computes its ground truth from the parameters that its data generator used [6]. CRMarena-Pro extends it to multi-turn conversations and to tests of confidentiality [7]. τ -bench compares the final state of a database with an annotated goal state [12]. TheAgentCompany grades long work tasks in a simulated software company by checking intermediate steps [11]. WorkArena and WorkArena++ evaluate browser agents on task templates over the demo data of ServiceNow [1, 2]. The Era by Eon benchmark generates a fictional company, serves its data through simulators of business applications, and computes an exact answer for each question [4]. In the Era by Eon benchmark, every rule that a question needs is stated in the question or in a document of the company. We call such questions *computable*. BIRD, a benchmark that translates questions into SQL, makes the same choice explicit: each question comes with an evidence sentence,

written by an expert, that states the outside knowledge that the question needs [10]. Spider 2.0 moves such questions to enterprise data warehouses [9].

This paper continues the Era by Eon benchmark. Its computable questions now barely separate strong agents. When agents can run code, each of the four strongest of six models answers between 22 and 25 of 27 computable questions correctly, with one run per question. Section 3 reports these results.

A business question can depend on a fact that no question or document states. Consider a customer that planned an *expansion*, which is an additional purchase on top of its existing contract. The CRM tracks this potential sale as a deal. The customer dropped the expansion, and the salesperson selected the loss reason “Timing - revisit next year” from a fixed list. On a recorded sales call, however, a person at the customer said that its board had cancelled the expansion because of an outage of the company’s service. The person identified the outage by the most recent urgent support ticket that the customer had opened before the deal closed. Urgent is the highest priority of a support ticket. An agent that reads only the CRM answers that the cause was timing, and this answer is wrong. To answer correctly, the agent must find the remark among many calls and recognize that it states the cause. It must then identify the ticket in the help desk. We call a fact of this kind *hidden knowledge*. This paper adds eight question templates to the Era by Eon benchmark. A template fixes the wording of a question and the rule that gives its answer. For a generated company, the benchmark selects a customer, a deal, or a salesperson from the company’s data. It fills the names of this entity into the template and computes the answer. A company that is generated with a different random seed has different data. The benchmark therefore selects different entities and computes different answers.

We evaluated 12 agents on the eight questions of one company, with three runs per question. Each agent pairs one of six language models with one of two agent programs, and every model ran in both programs. The best agent answered 18 of its 24 runs correctly. Claude Fable 5.1 and GPT-6 Astra are the two models with the most correct runs. For these two models, the ability to run code did not raise the number of correct runs. The hardest questions ask the agent to pick one record among several that look alike. For example, a customer received three renewal offers and signed one of them. Each offer states the last day on which its price holds, and only one offer was still valid on the day that the customer signed. Two questions of this kind were answered correctly in 1 of the 84 runs that all agents made on them.

This paper makes three contributions:

- (1) We define hidden knowledge, distinguish three kinds of it, and state four conditions under which a question that depends on it has one exact answer (Section 4).

- (2) We add eight question templates to the Era by Eon benchmark. We describe how the benchmark generates a question and its answer from each template without a language model, and how the question changes with the seed (Sections 5 and 6).
- (3) We evaluate 12 agents on the eight questions of one company and report where they fail (Sections 7 and 8).

2 Background: the Era by Eon benchmark

Era by Eon is a benchmark developed at Eon, the company of the authors. It generates a fictional company and simulates the business applications that the company uses [4, 5]. The input is a specification with five parts. They are an industry, a size class from micro to hyperscale, a business model such as selling to other businesses, a list of business applications, and a random seed. Generation is deterministic, so the same specification always produces the same company. The generator first builds a single data structure, the *entity graph*. The graph holds the company’s employees, customers, deals, support tickets, recorded calls, chat messages, and documents.

Each business application is served by a simulator. A simulator implements two interfaces of the real product. The first is its REST API, which is the web interface through which programs use the product. The second is its Model Context Protocol (MCP) server, which is a standard interface through which a language model calls tools. Salesforce and HubSpot are CRM systems. Zendesk is a help desk, and Jira tracks engineering work. Gong records sales calls and stores their transcripts. Slack is a chat system, and Amazon S3 serves as the file store. We call each item that a system stores a *record*. For example, a deal in Salesforce, a ticket in Zendesk, and a call with its transcript in Gong are records. We say that data is *served* when a simulator returns it to an agent. Agents have read-only access.

All simulators read from the same entity graph. As a result, a customer that appears in Salesforce also appears in Zendesk and in Gong with consistent details. Together, the simulators form a *digital twin* of the company. A digital twin is a software replica that behaves like a set of real systems. Here, each simulator behaves like its real product, and the data describes the fictional company. The data of the twin comes from one consistent entity graph. Its interfaces are the REST APIs and MCP servers of the real products. In a few places, the generator makes two systems disagree on purpose, in order to build questions of this paper.

Code computes the correct answer to each question from the served data. We call this answer the *key*. The *grader* is the program that compares an agent’s answer with the key. The generated companies are available at <https://console.era.eon.io> [3].

We use the following business terms. An *account* is a customer company, and a *contact* is a person who works at an account. A *deal* is a potential sale with an amount and an expected close date. A deal moves through *stages*, such as Qualification, Proposal, and Negotiation, until it is won or lost on its close date. A *contract* records the terms that an account has signed, and it covers a period called its *term*. A *renewal* extends a contract. A *proposal* is a document that states the price and terms of a renewal. The *pipeline* is the set of open deals. The *committed pipeline* is the amount that the sales team expects to close from the pipeline, and each company

computes it with its own method. A *ticket* is a support request. Jira stores work items called *issues* and groups them into *projects*. Each issue has a priority, which in our data is Highest, High, Medium, or Low. The *roadmap* is the planned engineering work in Jira. All amounts are in US dollars.

Unless stated otherwise, the experiments use one generated company. It is a large financial-technology (fintech) company that sells to other businesses, generated with a fixed seed. The generator’s size scale labels this company as having 1,000 employees. The generated data contains records for 40 of them, who are the users of the business systems. Of these 40, 17 work in engineering, 13 in customer support, 8 in sales, and 2 in presales. The company has 250 accounts, 4,190 contacts, 198 contracts, 2,500 deals in Salesforce, 3,000 tickets, 3,506 recorded calls, 9,880 Jira issues, 1,918 Slack messages, and 2,367 documents in the file store. HubSpot holds copies of 2,464 of the Salesforce deals. Some copies differ from the Salesforce deal in amount or close date.

3 Limits of computable questions

This paper continues the Era by Eon benchmark paper [4], which we call the benchmark paper. The benchmark paper evaluated agents on computable questions. We call a question *computable* when every rule that is needed to compute its answer is stated in the question or in a document in the company’s file store. A *rule* fixes a choice that the answer depends on. For example, a rule can fix the time window over which tickets are counted. This section first summarizes the benchmark paper. It then reports how agents that can run code perform on the current computable questions. These results motivate the questions of this paper.

The benchmark paper used its own agent program, which we call the *Era agent program*. In that paper, the model starts with three tools. The first lists the systems of the company. The second describes the tools of a chosen system’s MCP server, and the third calls one of these tools. The prompt does not list the tools of the MCP servers, so the model must discover which of them answer the question. The Era agent program cannot run code. The model must therefore read the records that it needs in tool results and compute the answer itself.

A run consists of *turns*. In each turn, the model receives the question, its own earlier responses, and the results of all earlier tool calls. It then writes one response. The response either requests tool calls or gives the final answer. When the response requests tool calls, the agent program runs them, and the next turn begins with their results. For example, in one turn the model may request the list of accounts from Salesforce. In the next turn, it may read this list and request the tickets of one account from Zendesk. One response can request several tool calls, so an agent program limits turns and tool calls separately. In the benchmark paper, a run was limited to 25 turns, 40 tool calls, and 8,000 characters per tool result.

In the benchmark paper, nine models answered 33 computable questions about a small fintech company. The company had 40 accounts and 240 support tickets. Each model answered each question three times. The share of correct runs ranged from 42.4% for GPT-5.4 mini to 76.8% for Claude Opus 4.8. The benchmark paper tested each of the 36 pairs of models for a statistically significant difference, with a correction for multiple comparisons. Only three

pairs showed one, and each of them compared GPT-5.4 mini with a stronger model. The benchmark paper also labeled each question with the capabilities that it tests. Averaged over the nine models, the share of correct runs was 3.7% on questions that chain several lookups and 92.6% on questions that only select records by a condition. In a chain of lookups, each lookup uses the result of the previous one. Aggregating every record of one type and ranking records were also among the hardest capabilities.

A script can perform these operations directly. It can follow a chain of lookups, read every record of one type, and sort the results. Only its printed output goes back to the model, so the model does not have to read thousands of records itself. We therefore asked whether agents that can run code answer computable questions correctly. For this purpose, this paper uses two agent programs. The first is a new version of the Era agent program, and the second can run code. We describe them in turn.

The new version of the Era agent program differs from the version of the benchmark paper in two ways. First, the agent can call the REST API of each simulator as well as its MCP server. The version of the benchmark paper used only the MCP servers. Second, a run may be longer. It may use up to 165 turns and 165 tool calls, and a tool result may have up to 32,000 characters. Like the earlier version, the new version cannot run code. In the rest of this paper, the Era agent program means this new version.

The second agent program is built with LangGraph [8], an open-source library for building agents that call tools. We call it the *LangGraph program*. It has the same tools as the Era agent program and one more tool, which runs Python code in a *sandbox*. A sandbox is an isolated Python interpreter. The sandbox has no network access of its own. A script sends its requests to the agent program, which forwards them to the REST APIs of the simulators. A script can therefore page through thousands of records and compute an answer. The two programs thus reach the same interfaces of the simulators, and they differ in code execution. A turn has the same meaning in both programs. In the LangGraph program, a response can also ask the sandbox to run a script, and the script’s printed output returns as the result of that tool call. The LangGraph program stops a run when the model gives its answer or after 150 turns. This limit is close to the 165 turns of the Era agent program.

We use 27 computable questions of the current version of the Era by Eon benchmark. These questions differ from the 33 questions of the benchmark paper in two ways. First, they were written for the large company of Section 2. Second, each of the 33 questions asks for one fact. Most of the 27 questions ask for several values about one subject, and a run is correct only when every value is correct. The following is one of the 27 questions: “For each account tier, what percentage of that tier’s accounts have at least one urgent support ticket that is still open?” A *tier* is one of three size classes of accounts. From largest to smallest, the tiers are Enterprise, Mid-Market, and SMB, which stands for small and medium-sized businesses. To answer, the agent must join the 250 accounts in Salesforce with the 3,000 tickets in Zendesk. It must then give three percentages, one for each tier.

We ran six models from three providers on these questions. They are Claude Fable 5.1 and Claude Sonnet 5 from Anthropic; GPT-6

Astra, GPT-5.6 Sol, and GPT-5.6 Luna from OpenAI; and DeepSeek-V3.2 from DeepSeek. We evaluate the same six models on the questions of this paper. On the computable questions, each model made one run per question in each program that it ran in. Table 1 shows which programs these were.

Table 1 shows the number of correct answers. With the LangGraph program, the four strongest models answered between 22 and 25 of the 27 questions correctly. Two of these four models also ran in the Era agent program, which cannot run code. There, GPT-6 Astra answered 8 questions and GPT-5.6 Sol answered 1. For these two models, code execution added 16 and 21 correct answers. GPT-5.6 Luna answered 8 questions with code and none without. DeepSeek-V3.2 answered one question without code and none with it. With code, the four strongest models are within three questions of each other. With one run per question, these counts give little evidence for ranking the four models. The scores cannot be compared with those of the benchmark paper, because the company, the questions, and the limits of the Era agent program differ.

Table 1: Number of correct answers on the 27 computable questions of the current benchmark, with one run per question. The Claude models were not run in the Era agent program on these questions, to limit cost.

Model	Era agent program (no code)	LangGraph program (with sandbox)
Claude Fable 5.1	not run	25
Claude Sonnet 5	not run	25
GPT-6 Astra	8	24
GPT-5.6 Sol	1	22
GPT-5.6 Luna	0	8
DeepSeek-V3.2	1	0

A script can read every record that a computable question needs and apply the rules that the question states. This likely explains why code execution added 16 and 21 correct answers for GPT-6 Astra and GPT-5.6 Sol. The questions of this paper depend on a fact that no question or document states. The records that seem to hold the answer show something else, and other served data implies the fact. An example is a remark by a customer on a recorded call. Section 4 defines such facts.

4 Hidden knowledge

Section 3 showed that the strongest agents answer most computable questions correctly when they can run code. In a computable question, the question or a document states every rule that the answer needs. This paper adds questions whose answer depends on a fact that neither the question nor any document states. We call such a fact a *hidden fact*. This section first explains hidden facts with one example. It then describes three kinds of hidden facts. Finally, it states four conditions that every question of this paper meets, so that each question has one exact answer.

Our example is a question about a service credit. A service credit is a discount that a customer receives when the company does not provide the service that the contract promises. The benchmark generates this question from a template, which Section 5 describes.

For the company of Section 2, the template selects the customer Dovewood Analytics. For a company that is generated with another seed, the template selects another customer. The agent receives the following question:

What SLA credit is Dovewood Analytics actually owed on its current contract? Answer a JSON object with exactly these keys: `credit_pct` (the credit as a bare percentage number), `effective_month` (the first month it applies, YYYY-MM), and `months_covered` (how many calendar months from that month through the month the served contract ends, inclusive).

The question asks about a contract, and Salesforce stores the company’s contracts. Dovewood Analytics has one contract, whose term is 19 September 2023 to 19 September 2024. The contract record has a field that holds the service credit in percent. For this contract, the field holds 0. An agent that relies on this field answers that Dovewood Analytics is owed no credit. This answer is wrong, because the credit was promised on a recorded call and Salesforce does not record the promise.

The promise is in Gong. On 22 August 2024, Ana Dalewick, the salesperson who manages the Dovewood Analytics account, took part in a call with two employees of Dovewood Analytics. At the end of the call, she says:

On the credit, here is what I’m putting on the table, and I’ll own that it is not in the contract paperwork yet: five points off for every calendar month of this term in which you’ve had to open an urgent-priority ticket with our desk, capped at fifteen, and it runs from the first month that happened. Hold me to it.

The remark states a rule but no dates. The agent must apply the rule to the tickets in Zendesk. Zendesk stores eleven tickets of Dovewood Analytics, and four of them have the priority urgent. They were opened on 6 December 2023, 1 March 2024, 31 May 2024, and 18 September 2024. They fall in four different months of the contract term. At five points per month, the credit would be 20 percent, so the cap of 15 percent applies. The credit starts in December 2023, the month of the first urgent ticket. From December 2023 through September 2024, the month in which the contract ends, there are 10 months. The key is therefore a credit of 15 percent that starts in December 2023 and covers 10 months.

4.1 Definition

The promised credit rule is an example of a hidden fact. A hidden fact has three properties. First, the key depends on it. Second, neither the question nor any document in the file store states it, and the records that the question asks about do not show it. Third, other served data gives evidence for it. In the example, the key depends on the promised rule. Neither the question nor any document mentions the promise, and the contract record shows a credit of 0. The evidence is the remark on the call in Gong. The second property separates hidden facts from the rules of computable questions. The question or a document states those rules.

4.2 Three kinds of hidden knowledge

The eight questions of this paper fall into three kinds. In four questions, the evidence for the hidden fact is a remark on one recorded call. The service-credit question is one of them. In three questions, several records seem to answer the question, and the agent must find out which of them the company relies on. In one question, the agent must work out from an old report how the company computes an amount. Section 6 describes each question.

4.3 Conditions for an exact answer

A question that depends on a hidden fact must still have one answer that a program can grade. The benchmark checks four conditions for every question. Section 5 describes how.

- (1) **The evidence is served.** The benchmark computes the key from the data that the simulators return. In the example, this data is the remark in Gong, the tickets in Zendesk, and the contract in Salesforce.
- (2) **The answer is unique.** Under the rule that the key uses, the data allows exactly one answer. In the example, Dovewood Analytics must have exactly one contract, so that the question names one contract.
- (3) **The obvious answer is wrong.** An agent that reads only the record that the question asks about gives a wrong answer. In the example, this record is the contract, which shows a credit of 0. The key is a credit of 15 percent.
- (4) **The answer is exact.** The answer consists of two or three values, such as a number, a month, or a name. The question states the form of each value. For example, the service-credit question asks for the month in the form 2023-12. An answer is correct only if all of its values are equal to the key.

5 From templates to questions

Section 4 showed one question and traced its answer through three systems. Nobody wrote that question by hand. It came from a *template*, which is a recipe that produces one question of its kind for any generated company. This paper adds eight templates to the benchmark, and each of them produces one question for a company. This section tells how a template becomes a question. We follow the service-credit question of Section 4 from the moment the company is generated to the moment the agent reads the question. At the end of the section, we generate a second company with another seed and show that the same template produces a different question with a different answer. Figure 1 shows the service-credit template, part by part.

Everything begins with the company. The generator builds it from the specification and the seed, as Section 2 described. It creates the employees, the customers, their contracts, their support tickets, the recorded calls with their transcripts, and the documents in the file store. No template has run at this point. Dovewood Analytics is one customer among 250. It has a one-year contract, and it has opened eleven support tickets, four of them urgent. Its contract shows a service credit of zero, and none of its 23 recorded calls mentions a credit. Nothing in the company yet points to the question that the agent will later receive.

Template: service credit		Systems: Salesforce, Zendesk, Gong
Search rule	a contract whose customer opened urgent tickets in at least two different months of the contract term; take the first candidate in a fixed order	
Hidden fact	credit_pct = 5 points per such month, capped at 15 effective_month = the first such month written to the answer file only; no system changes	
What the systems show	Salesforce, object Contract, field SLA_Credit_Pct__c = 0	
Clue	call: the customer's last recorded call after the first urgent month and before the contract ends speaker: an employee of the company who is on that call text: "On the credit, here is what I'm putting on the table, and I'll own that it is not in the contract paperwork yet: five points off for every calendar month of this term in which you've had to open an urgent-priority ticket with our desk, capped at fifteen, and it runs from the first month that happened. Hold me to it."	
Question	"What SLA credit is {customer} actually owed on its current contract? Answer a JSON object with exactly these keys: credit_pct, effective_month, months_covered."	
Checks	the contract's credit field is 0 the customer has exactly one contract at least two months of the term have an urgent ticket recomputing the hidden fact from the records gives the same values	
Key	credit_pct, effective_month, months_covered; the answer is correct only if all three match	

Figure 1: The service-credit template. The first four parts run in the generator and shape the company. The last three run when the benchmark is assembled and produce the question and its key.

The service-credit template now searches the finished company for a customer to ask about. It looks for a customer whose support tickets show a pattern that would justify a credit. The pattern is urgent tickets in at least two different months of the same contract term. Many customers of this company fit, and the template needs one of them. It sorts the candidates in an order that depends only on their identifiers and takes the first. This order is the same on every run, so the same company always produces the same question. In this company, the template arrives at the contract of Dovewood Analytics. That contract ran from 19 September 2023 to 19 September 2024, and the four urgent tickets of Dovewood Analytics fall in four different months of that term.

With the customer chosen, the template invents what the company promised. It counts the months of the term in which Dovewood Analytics opened an urgent ticket. Four months qualify, which gives five points each and twenty in total, and the promise caps the credit at fifteen percent. The credit runs from December 2023, the first of those months. The template writes these two values and the rule that produced them into a file that belongs to the benchmark. This file never reaches any simulator, so no agent can read it. It holds the answer that the grader will later expect. The company's own systems are left as they are, and the contract of Dovewood Analytics still shows a service credit of zero.

The promise now exists only in the benchmark's file, so the template has to give the agent a way to discover it. It does so with one sentence spoken on a recorded call. The template goes through the calls that Dovewood Analytics held between December 2023, the first month with an urgent ticket, and the end of the contract. There are eight such calls. It takes the last of them, the call of 22 August 2024 in which Ana Dalewick discussed a new deal with two

employees of Dovewood Analytics. To the end of that transcript, the template adds the remark that Section 4 quoted, spoken by Ana Dalewick. Nothing else in the call changes, and the earlier turns do not lead up to the remark. This is the only change that any template makes to the company. The remark states the rule of the promise but none of its numbers. The agent has to work out the months, the percentage, and the duration from the tickets and the contract.

The company is now complete, and the simulators take over. Each of them serves its part of the company to the agent: Salesforce serves the contract with its credit field of zero, Zendesk serves the eleven tickets, and Gong serves the 23 calls, including the one that now ends with the remark. Before the agent sees anything, the benchmark performs its own check. It fills the name Dovewood Analytics into the question text and computes the answer again, this time only from what the simulators serve. It requires that Dovewood Analytics has exactly one contract, that the credit field of this contract holds zero, and that the recomputed credit and starting month agree with the values in its file. If any of these checks fails, the benchmark drops the question for this company rather than ask a question with a doubtful answer. If all of them pass, the agent receives the question, and the grader later compares the agent's three values with fifteen percent, December 2023, and ten months.

Two things hold for every step of this story. First, no language model takes part in it. Code generates the company, including every transcript and document, code chooses the customer, code writes the remark, and code computes the answer. The questions and their answers therefore contain no model errors. Second, every step is deterministic, so the same specification and seed always give the same company, the same customer, and the same answer. The other

seven templates follow the same path. Each of them needs at least two customers of the right kind to choose from. We measured these counts for the fintech companies only, and the four companies of the sizes mid, large, enterprise, and hyperscale have enough for every template. The benchmark therefore adds the eight questions to these four companies.

Two things hold for every step of this story. First, no language model takes part in it. Code generates the company, including every transcript and document, code chooses the customer, code writes the remark, and code computes the answer. The questions and their answers therefore contain no model errors. Second, every step is deterministic, so the same specification and seed always give the same company, the same customer, and the same answer. The other seven templates follow the same path. Each of them needs enough customers of the right kind to choose from. Companies of the size mid or larger have enough data for all eight questions, and smaller companies have too few customers of some kinds.

To see what the seed changes, we generated the same company a second time, with seed 43 instead of 42 and everything else unchanged. The second company also has 250 customers and 2,500 deals, but most customers have other names, and their contracts, tickets, and calls differ. The service-credit template ran on this company as described above and chose the customer Swinburn Holdings. Its contract, like Dovewood’s, has urgent tickets in at least two months of its term, and the template’s fixed order placed it first. The question text is the same apart from the name, and the remark is the same sentence on a different call. The answer depends on the customer. A customer with urgent tickets in exactly two months would be owed ten percent. Both Dovewood Analytics and Swinburn Holdings had more such months, so both reach the cap of fifteen percent, from December 2023 in both cases. The number of months differs: ten for Dovewood Analytics and thirteen for Swinburn Holdings, because the contract of Swinburn Holdings ends three months later.

6 The seven other templates

Figure 1 showed one template. The other seven follow the same structure and fall into the three kinds of Section 4. This section explains each kind and then states, for each template of that kind, what it looks for, what the truth is, and what the question asks. The names in bold are the names by which the rest of the paper refers to the questions.

6.1 A remark on a call

In four templates, the clue is a remark on a recorded call. The customer’s records are complete and consistent, and they suggest an answer. Salesforce shows a loss reason for a lost deal, a recent activity date for a contact, or a credit of zero on a contract. The template leaves these records as they are. It adds one remark to one of the customer’s recorded calls. The remark states a rule for computing the real answer from the records. For the service credit, the rule is five points per month with an urgent ticket, capped at fifteen. The answer itself is never said on the call and is never stored in any system. It is stored only in the answer file. The agent has to find the remark, understand the rule, and compute the answer

from the records. Figure 1 showed one of the four templates. The other three follow.

Lost deal. The customer says on a call that a lost deal was waiting on a roadmap story of the engineer who handled most of its bugs, and the question asks which story. For the company of Section 2, the agent receives:

The Soleris Partners opportunity Soleris Partners – Platform Rollout (closed 2024-07-31) was lost. Answer a JSON object with exactly these keys: blocker (the key of the roadmap issue in the tracker, e.g. PLAT-12, that the deal was actually waiting on when it was lost) and amount (the opportunity’s amount as the CRM serves it, a bare integer).

Departed contact. The customer says on a call that a regular participant has left the month after their last call, and the question asks who left and when. For the company of Section 2, the agent receives:

Which of the Turquoise Systems contacts who used to be on the calls is no longer at the company? Answer a JSON object with exactly these keys: contact (their full name as the CRM spells it), departed (the month they left, YYYY-MM), and still_active_in_crm (true if the CRM still shows activity for them dated 2024-08 or later).

Dropped expansion. The customer says on a call that it dropped an expansion because of the outage behind its last urgent ticket, and the question asks for the cause, the ticket, and the lost amount. For the company of Section 2, the agent receives:

Seraphis Group passed on an expansion: the opportunity Seraphis Group – Data Retention Add-on closed lost and the account renewed on its existing terms instead. Answer a JSON object with exactly these keys: cause (one of requirements, pricing, incident, competitor, budget – what actually drove the decision), ticket (the support ticket’s external id, e.g. fin-large-ticket-1-0, that the cause traces to, or null), and arr_delta (the lost opportunity’s CRM amount minus the annual value the renewal proposal in the document store states for the served contract’s term, a bare integer, negative when the renewal is larger).

6.2 Several records, one is right

In three templates, no call carries a clue. The company holds two or more records that all seem to answer the question, and only one of them is the record that the company relies on. The template writes which one into the answer file and changes nothing in the systems. The evidence is already in the records: a property that names the system of record, the date on which a project stopped changing, or a line on a document that says until when its price holds. The agent has to notice this evidence and set the other records aside.

Conflicting amounts. Salesforce and HubSpot record one deal with different amounts, and the question asks which amount the

forecast commits and for which fiscal quarter. For the company of Section 2, the agent receives:

The Berylpeak Labs deal Berylpeak Labs – Initial Rollout created on 2023-05-09 is tracked in both CRMs with different amounts and close dates. Which number is the one committed in the forecast, and for when? Answer a JSON object with exactly these keys: `amount` (the committed amount, a bare integer) and `quarter` (the fiscal quarter it was committed for, in the form FY2025Q2).

Roadmap. Jira holds an old roadmap project that stopped changing and a new one that is live, and the question asks which engineer has the most open roadmap stories. For the company of Section 2, the agent receives:

Which engineer currently carries the most open roadmap stories, and how many? Answer a JSON object with exactly these keys: `engineer` (their display name as the tracker serves it) and `open_stories` (the number of Story issues assigned to them that are not Done, a bare integer).

Signed proposal. The file store holds several rounds of one renewal proposal with different uplifts, and the question asks which round the customer signed and what uplift it carries. For the company of Section 2, the agent receives:

Which renewal proposal round did Evidora Logistics actually execute for its current contract, and what uplift did it agree to? Answer a JSON object with exactly these keys: `term_start` (the term start date that proposal states, YYYY-MM-DD) and `uplift_pct` (the uplift percentage its commercial summary states, a bare integer).

6.3 A method in an old report

In one template, the clue is a report in the file store. The report shows the results of a computation on the day it was written, but it does not state the rules of the computation. The company’s people know the rules and apply them to the current records. The template writes the rules and today’s result into the answer file and changes nothing in the systems. The agent has to recover the rules from the rows of the report and run them again on the records as they are today.

Pipeline. A pipeline review lists a salesperson’s deals with a committed amount for each, and the question asks what the salesperson’s committed pipeline is today under the review’s own rules. For the company of Section 2, the agent receives:

RevOps’ pipeline review for Sara Novak in the document store is a snapshot. What is Sara Novak’s committed pipeline today under that review’s own commit model, run against Salesforce as it stands now? Answer a JSON object with exactly these keys: `committed_pipeline` (the total the model commits, a bare integer in dollars) and `opportunities_counted` (how many

of their opportunities the model counts, the way the review’s total row counts them, a bare integer).

7 Experimental setup

We now run agents on the eight questions of Section 6. The question we want to answer is simple: can an agent that reads the company’s systems find the hidden facts, and does the ability to run code help? This section states what we ran and how we scored it. Section 8 gives the results.

Agents. An agent is one language model paired with one agent program. We use the six models of Section 3 and the two agent programs of Section 3, the Era agent program, which cannot run code, and the LangGraph program, which can. Every model ran in both programs. This gives twelve agents.

Limits. The two programs keep the limits of Section 3. Two further limits apply in these experiments. The Era agent program stops a run after 150,000 tokens of model output. The LangGraph program stops a run after one hour, and one script in its sandbox may run for at most five minutes.

Access. The agent can read from the systems and cannot write to them. The sandbox cannot see the benchmark’s own files: the generated data, the keys, and the answer file. The agent reaches the company only through the systems, like an employee.

Runs. Each agent answers each question three times. A run ends when the agent gives its answer or reaches a limit. Each agent therefore has 24 runs.

Grading. The agent gives its answer as a JSON object with the fields that the question names. A run is correct when every field equals the key. A run with some correct fields is incorrect. An abstention is incorrect, because every question has an answer. A run that reaches a limit without an answer is incorrect.

What we report. For each agent, we report the number of correct runs out of 24 and a 95% confidence interval for the share of correct runs, computed with the Wilson method. We also report how many runs were abstentions. For comparison, we give the number of the 27 computable questions of Section 3 that the agent answered correctly, one run per question. This shows whether an agent that is strong on computable questions is also strong on hidden knowledge.

8 Results

Table 2 gives the results. Two models stand apart. Claude Fable 5.1 answered 18 of its 24 runs correctly in the Era agent program and 15 in the LangGraph program. GPT-6 Astra answered 13 and 12. The other four models answered at most 6 of 24 in either program. We now look at the three kinds of question in turn, then at what the agents did on the hardest ones.

A remark on a call. On the four questions of this kind, the twelve agents answered 54 of 144 runs correctly. Claude Fable 5.1 in the Era agent program answered all twelve of its runs. In the LangGraph program it answered nine, and each GPT-6 Astra agent also answered nine. The departed-contact question was the easiest of the eight: 21 of its 36 runs were correct. The lost-deal, dropped-expansion and service-credit questions were correct in 10, 13 and 10 of 36 runs.

Table 2: Results of the 12 agents on the eight questions, with three runs per question. The interval is a 95% Wilson interval for the share of correct runs, in percent. Abstained counts runs out of 24. The last column counts the computable questions that the agent answered correctly, out of 27, with one run per question. “Not run” means that the agent did not run on the computable questions.

Model	Agent program	Correct runs (of 24)	95% interval	Abstained	Computable (of 27)
Claude Fable 5.1	Era	18	55.1–88.0	0	not run
Claude Fable 5.1	LangGraph	15	42.7–78.8	0	25
GPT-6 Astra	Era	13	35.1–72.1	5	8
GPT-6 Astra	LangGraph	12	31.4–68.6	5	24
Claude Sonnet 5	Era	6	12.0–44.9	2	not run
Claude Sonnet 5	LangGraph	6	12.0–44.9	0	25
GPT-5.6 Sol	LangGraph	2	2.3–25.8	0	22
GPT-5.6 Sol	Era	1	0.7–20.2	1	1
GPT-5.6 Luna	Era	1	0.7–20.2	7	0
GPT-5.6 Luna	LangGraph	0	0.0–13.8	7	8
DeepSeek-V3.2	Era	0	0.0–13.8	14	1
DeepSeek-V3.2	LangGraph	0	0.0–13.8	3	0

Several records, one is right. These three questions were the hardest. The conflicting-amounts question was correct in 7 of 36 runs: all six runs of Claude Fable 5.1 and one run of GPT-6 Astra in the Era agent program. Here the evidence is a property on the HubSpot record that names Salesforce as the system of record. The roadmap question was correct in none of its 36 runs. The signed-proposal question was correct once, by GPT-5.6 Luna in the Era agent program. On these two questions, ten of the twelve agents had both values wrong in every run. The six runs that Claude Fable 5.1 failed in the Era agent program are exactly its runs on these two questions.

A method in an old report. The pipeline question was correct in 12 of 36 runs. All twelve came from the four agents of Claude Fable 5.1 and GPT-6 Astra, and each of them answered all three of its runs.

How much the agents searched. For each agent and question, we averaged the number of tool calls over the three runs. A call to the sandbox may read many records, so this counts actions, not data. For the four agents of Claude Fable 5.1 and GPT-6 Astra, the roadmap and signed-proposal questions had the two lowest averages of the eight questions, between 7 and 17 calls. On the other six questions, the same agents made between 17 and 109 calls. None of the four abstained on the two hardest questions. They answered quickly, and wrongly.

Does code help? On the computable questions of Section 3, code helped GPT-6 Astra a great deal: 24 correct in the LangGraph program against 8 in the Era agent program. On the eight questions of this paper, it did not: 12 against 13. Claude Fable 5.1 answered 15 runs with code and 18 without.

The weaker models. Claude Sonnet 5 answered 6 runs in each program. DeepSeek-V3.2 answered none. In the Era agent program it abstained in 14 of 24 runs, and in the LangGraph program it reached the turn limit without an answer in 19 of 24. GPT-5.6 Luna abstained in 7 of 24 runs in each program.

9 Discussion

The results separate two abilities. The first is to compute over the data. With code, the strongest models answer nearly every computable question of Section 3. The second is to know which records the company relies on and which rule applies to them. The eight questions of this paper test the second ability, and the strongest models pass only part of the test.

The three questions about several records show where the line falls. In the conflicting-amounts question, one property on the HubSpot record names the system of record, and Claude Fable 5.1 found it in every run. In the roadmap and signed-proposal questions, nothing names the right record. The agent has to notice that one project stopped changing on a given day, or that only one proposal’s price hold covered the signing date. All twelve agents together answered these two questions once in 72 runs. On the same two questions, the four strongest agents made fewer tool calls than on any other question and never abstained. The pattern is consistent with an agent that reads the record the question names, finds a plausible value, and stops.

Code did not help on these questions, although it helped a great deal on the computable ones. A sandbox makes it easy to read many records. It does not tell the agent which of them the company relies on.

The missing knowledge is small. It is a handful of facts of the kind that an employee learns in the first weeks: which system holds the committed amount, on which day the roadmap moved, how the pipeline review is computed. A written store of such facts would turn the hidden facts of this paper into recorded ones. The benchmark can measure how much such a store helps, by running the same agents with and without it.

10 Limitations

All results come from one company and one seed. The templates produce questions for other seeds as well, and the eight questions of the seed-43 company pass the checks of Section 5, but we have not run agents on them. Each agent has 24 runs, so the 95% intervals are up to 37 percentage points wide, and most differences between

agents are not statistically supported. We have not measured how well a person answers the eight questions from the systems alone. The remark on each call is the same sentence in every company, so a model could learn to recognise it.

The generated data has defects that a reader of the questions should know. In the four templates with a remark, the remark is the last turn of a call whose other turns do not refer to it. In the lost-deal and dropped-expansion templates, the rule in the remark selects a record by its assignee, priority and dates, not by its content.

The six models come from three providers, and the results may differ for other models. The result files record, for each run, whether the answer was correct, which of its values were correct, whether it was an abstention, and how many tool calls were made. They do not record the answers or the tool calls themselves, so we cannot say which wrong answers the agents gave. The results describe the models and agent programs available in September 2026.

11 Conclusion

Agents that can run code now answer most questions whose answers are in a company’s records. We extended the Era by Eon benchmark with eight question templates whose answers depend on hidden knowledge: a promise made on a call, the record that the company relies on among several, or the rules behind an old report. For every generated company, the benchmark fills each template from the company’s own data and computes the answer without a language model. The evidence for each answer is in the systems, but not in the record that the question names.

On the company of this paper, the best agent answered 18 of 24 runs, and four of six models answered at most 6. Every agent found the rule when a person stated it on a call, at least some of the time. Almost no agent found the right record when only dates and small marks in the data pointed to it: two such questions were answered once in 72 runs. Code, which decides the computable questions, did not help here. The next step is to give agents a written store of the facts that employees know, and to measure with this benchmark how much of the gap it closes.
